REVISED MAY 1983

300 FOOT TELESCOPE

West longitude:
Latitude:
Height above sea level:
Diameter:
Focal length:
f/D:
Declination limits:
Pointing accuracy:
$79^{\circ} 50^{\prime} 56!36$
$38^{\circ} 25^{\prime} 46$ ". 3
894 m
91.4 m (300 feet)
38.7 m (127 feet)
0.424
$-18^{\circ} 30^{\prime}$ to $89^{\circ} 50^{\prime}$
typically $30^{\prime \prime}$ rms, $10^{\prime \prime}$ rms at 6 cm
$5 \mathrm{GHz}, 6 \mathrm{~cm}$

## PREFACE

The preface to the previous edition of this manual contained an explicit disclaimer that the successful operation of an observing program is ultimately the observer's responsibility, although the NRAO will provide all possible assistance. This philosophy has not changed, but the disclaimer has been moved to an equally prominent setting: Chapter 1, page 1. The observer should feel free to direct inquiries at any time to the electronics staff, computer programmers, and especially the "friend of the telescope". The format of this manual has changed, and so this preface will serve as a guide to using this manual.

An effort has been made to separate out the reference material from the "cookbook" material. Chapter 1 contains an introductory overview of the observing system and the contents of later chapters. The material in Chapters 2 through 7 is primarily reference material, while Chapters 8 through 10 contain the actual guides to preparing an observing program, along with very brief reviews of topics explained more fully in the earlier chapters. Chapter 8 consists of a discussion of the task of getting the telescope on source, obviously relevant to all observations. Chapters 9 and 10 consist of descriptions of spectral line and continuum observing, respectively. Some repetition was unavoidable while striving to make these two chapters independent of each other.

Observers generally familiar with the 300 foot, needing reminders of the input card formats will find that material in the later chapters. New observers may also wish to begin with these later chapters (after reading Chapter 1 ), referring back to the material in the earlier chapters as required or desired. Those observers who read straight through this manual will find material organized (more or less) in the order of the signal path, from front end to back end.

The text for this manual has been prepared on an IBM Displaywriter. This greatly simplified the major format changes, and should help to keep things up to date in the future. On the other hand, it is not very easy to interleave text with figures and tables, and so these can be found at the end of each chapter.

## 1. INTRODUCTION

This document describes the use of the 300 foot telescope for making astronomical observations. It consists of a compilation of the properties of the observing system requiring decisions, or at least an awareness, by the observer, along with a guide to preparing an observing program. This manual is intended as a guide to setting up an observing program which runs under computer control. The topic of data reduction is treated in separate documents, one each for line and continuum observations.

The reason for the existence of this manual is quite basic: the responsibility for the successful operation of an observing program rests with the observer. While the NRAO assumes many of the details of receiver set-up and telescope control, and equipment maintenance, the observer is expected to make enough on-line checks to insure that everything is working properly. It seems reasonable to expect that the observer should understand the equipment well enough to mentally trace a signal from the sky to the recording device. Many things are not obvious from looking at front panels, so some very fundamental questions to the staff may be in order. Everyone at the NRAO appreciates the fact that an observer cares enough about the experiment to understand the equipment about to be used.

The observer's basic responsibilities are to make equipment requirements known to the electronics staff in plenty of time, to provide the telescope operator with telescope control cards and receiver operation instructions, and to monitor and reduce the output data. Normally the observer on an assistant is expected to be in Green Bank during the entire run, and it is strongly suggested that the observer be in Green Bank from 1 to 7 days (depending on previous experience) before the start of the run to become familiar with current procedures. One or more of the scientific staff acts as "Friend of the telescope" and may be called upon at any time to answer questions or refer the observer to someone who can.

For the purposes of discussion, the chapters that follow describe the observing system broken down into components: (2) the telescope structure and its physical limitations, (3) some of the basic properties of receivers and feeds, (4) the problem of pointing, (5) the intermediate frequency system and continuum detectors including the digital continuum receiver, (6) the Model III autocorrelation spectrometer, and (7) the problem of interference. There are three computers in the system as well. The computers process and record the digitized detected signal at the end of the signal path, but they also control vital parts of the system so that observing can be more or less automatic. The chapters describing the system hardware take note of the points where computer input is available or required, but the step-by-step discussion of preparing the computer input for automated observing is deferred to later chapters which describe: (8) pointing the telescope, (9) spectral line observing, and (10) continuum observing. Computer input is in the form of punched card decks. One computer (the H316) is dedicated to positioning the telescope, and it needs to know about the pointing corrections. A second computer (the DDP116) runs the observing program
and handles the data, and it needs to know how to configure the receiving system and what sequence of operations the observer wants to perform. The third computer (the MODCOMP) passively receives data from the DDP116 and is for interactive data processing, primarily using the POPS/CONDAR reduction programs.

This chapter is intended to provide an overview of the operation of the 300 foot telescope and its supporting electronics. The first section deals with hardware, and describes in general terms the set-ups for line and continuum observing. The second section deals primarily with software -- the POPS/CONDAR data reduction programs, and the properties of data transfer to the MODCOMP analysis computer. These sections show how the components of the observing system fit together as a guide to the detailed discussions in later chapters, and are not meant to standardize observing procedures. The observing system is very flexible, although somewhat cumbersome, and the observer is encouraged to plan an observing program around the best technique for the purpose and not around standard set-ups and reduction programs.

Under most circumstances, observing programs are run under computer control. However, the value of the telescope operator to a successful observing program should not be overlooked. Intervention by the operator, under instructions from the observer, to retune or change gains expands the flexibility of the whole system. At the observer's request, the operator can provide additional documentation on the log sheets, if necessary. Through experience, the operators have seen most of the things that can go wrong with the equipment, and are helpful in recovering from errors. Also in the category of parts of the system that talk back is the "Friend of the telescope," a resident advisor on the system with an astronomical perspective. The Friend may be the most useful advisor on adapting the system to the goals of a particular observing program. Finally, the computer programmers are the best source of information about the observing and data reduction programs.

The final two sections deal with day-to-day operations: scheduling, and daily routine. Unlike previously discussed parts of the system, these aspects have evolved slowly to their current state for the protection of the observer's data and priority.

### 1.1. OBSERVING HARDWARE

The two most commonly used receiver configurations, for line and continuum observing, are shown in Figures $1-1$ and $1-2$, respectively. A third, labeled "Pulsar system", might have been included, but it would essentially be a slight variation on Figure 1-2, with a specialized post-detection processor. The feed combination and number of data channels vary from one front end to another, so the diagrams are meant only to be representative. For more detailed information on a particular system, consult the receiver installation sheet normally given to the observer at the time of observing, or the appropriate electronics division internal reports, available on request, or talk to the engineer responsible for that receiver. Those properties of the telescope itself
which are independent of the receiver/feed combination, such as rates and limits, are discussed in Chapter 2. A more detailed, but still largely receiver independent discussion of the properties of receivers and feeds is found in Chapter 3.

The intermediate frequency (IF) stages follow the front end box. In the spectral line system (Figure l-1), the primary frequency determining element is the Universal Local Oscillator (ULO), which operates in the range of $250-500 \mathrm{MHz}$. The ULO is a computer controlled variable frequency synthesizer. A frequency counter continuously monitors the output frequency to ensure that it is equal to the commanded frequency. The ULO output frequency is multiplied up once or twice, depending on the receiver, by factors of 2 to 8 to equal the sky frequency plus or minus the IF. A set of variable local oscillators (VLO's) is provided for the second conversion, so that the sky frequency of two or more channels can be offset by using different IF's with a single ULO. The amount of offset is restricted only by the bandwidths of the front end and first IF amplifiers. Frequency switching is easily implemented under computer control.

The ULO may also be part of the continum IF section, although most of its features are usually not needed. Frequency settings can be made manually.

The detector in the spectral line set-up is the Model III autocorrelation spectrometer. After appropriate filtering and conversion to baseband, the autocorrelator digitally samples the signal and forms the autocorrelation function, which is sent to the DDP116 computer. A Fourier transform is performed by the DDP116, which produces a spectrum to be written on magnetic tape, displayed on a monitor oscilloscope, and transmitted to the MODCOMP analysis system. Since absolute amplitude information is lost in one-bit sampling by the autocorrelator, the output of a total power monitor, with and without a calibration noise signal, is also recorded on tape for scaling the spectrum in the final reduction.

The autocorrelator sends signals which control frequency switching and the calibration noise source, so it is more than a digital filter. Observing bandwidths and correlator configuration are set manually on the front panel of the correlator, but the settings are compared to those specified on instructions to the DDP116 computer. The autocorrelator receives instructions to start and stop taking data from the DDP116 computer.

Multiplexed square law detectors and $A / D$ converters sampled by the DDP 116 make up the "analog" continuum detectors. The A/D's are typically sampled every second or so, with a minimum sample time of 0.5 . The computer can automatically calibrate the data by periodically turning on the calibration noise signal ("pulsed cal"). Without pulsed cals, sample times of 0.1 to 0.4 in steps of 0.1 can be reached. A fast sampling program is available for pulsar work with sampling times as short as 1 millisecond, but it is not normally used for continuum work.

A digital radiometer system is also available for continuum observing. This is a new modular system providing modern features and improvements over the analog system. The analog system described above is computationally limited to elementary functions such as simple gain modulation balancing and analog subtraction for the Dicke switch mode, while occasionally providing for short integration features. The new digital system does all of this and more. Many complex computations are performed in real time as well as novel digital techniques for gain modulation Dicke switching, thus providing very stable and reliable operating characteristics. Combined with the very stable cooled GaAsFET front ends now available, reliable observations in the total power mode are possible. References for the digital receiver are Hallman 1978 [51] and Fisher 1978 [52].

### 1.2. DATA HANDLING

Digitized data from the autocorrelator, digital receiver, or multiplexed $A / D$ 's are received by the DDP116 computer. Spectral line data are Fourier transformed and scaled to form a calibrated spectrum. Frequency switched data are properly differenced. Continuum data from the $A / D ' s$ are scaled if the pulsed cal method of calibration was used. The digital receiver passes already calibrated data to the DDP116. In each case the data are recorded onto a nine-track, 1600 BPI tape. These data tapes are normally sent to the NRAO Computer Division in Charlottesville for storage. In the event of a failure of the MODCOMP analysis computer, raw data are not lost, and may be retrieved from the telescope tape.

One of the most basic operations in sequencing a series of observations is sending timing signals to start and stop data taking. (The other basic operation is positioning the telescope on source, and obviously these two operations must be synchronized.) Start and stop times are specified by the observer, and passed on by the DDP116 computer. The uninterrupted block of data accumulated between start and stop times is a scan, which is identified by a scan number as well as other information concerning the system configuration. The identifying information is stored in a header which accompanies the data themselves on tape and in the analysis computer. A spectral line scan consists of a spectrum for which the total integration time is the difference of stop and start times. A continuum scan is a time series of samples of the radiometer output. A scan may consist of a number of subscans, called records since each corresponds to a physical record on tape. A record is the smallest amount of data which may be edited out if there is some problem with it.

Records are passed to the MODCOMP analysis computer where they are accumulated to form a single scan. It is not possible to edit bad records on the analysis computer. The accumulated scans are stored on a disk where they can be read but not changed. This disk can accommodate a total of 2560 spectral line scans plus 1600 to 2560 continuum scans, depending on their length. When the end of the available disk storage space is reached, the storage "wraps around"; i.e., the most recent scan overwrites the oldest one. Since the observer has no way of preventing
this from happening, it is useful to estimate ahead of time how fast the disk will fill (based on the time per scan and number of scans per day), and to schedule data reduction in such a way that scans are not lost before they can be processed. If the telescope schedule is being shared with another observer, the number of scans produced under the other program(s) must be taken into account since there is only one data file of each type.

The on line analysis computer is available to the observer only during the observations. There is, however a duplicate analysis system in the Jansky Lab which can be used by reading in the telescope tapes or KEEP tapes. KEEP tapes are a way to save and transport reduced data, as described in the POPS/CONDAR manuals, and generally are a better archival medium than telescope tapes. Although KEEP tapes and telescope tapes are normally written at 1600 BPI, the MODCOMP can write 800 BPI tapes.

Off site data reduction can be done on the IBM 4341 computer in Charlottesville. Standard data reduction programs are available, or the observer may do as much of the programming as is desired. An observer desiring to make use of the Charlottesville computer should call extension 250 in Charlottesville to make the necessary arrangements.

Regardless of whether the observer will do any off-line data reduction, it is important to have a personal observer number, obtained from the computer department in Charlottesville. In contrast to project numbers assigned to proposals, an observer number or user number is permanently assigned, and follows an observer through life. This number is used to identify data on tape in the library in Charlottesville, and to keep some order in the tape library for the benefit of the observers. A single user number may suffice for a group of observers, but in NRAO files a single name is associated with each user number.

### 1.3. THE TELESCOPE OPERATOR

As mentioned in the introduction, the telescope operator's role in a successful observing program should not be overlooked. The operators have some general familiarity with the equipment, and are quite helpful when something goes wrong with the equipment. The operators know who to call when something goes wrong.

In the course of normal observing the operator can make routine adjustments in the system configuration, such as bandwidths, IF frequencies, gains, and autocorrelator configuration, on instructions from the observer. Observers have used such schemes as color coded source cards and notes written on source cards, as well as a sheet of written instructions, to insure that these changes follow the desired sequence. No scheme is foolproof since the operator may sometimes be away from the observing console. The header information accompanying the data may be insufficient to document whether a desired change actually took place, so in general it is desirable to keep the number of manual system reconfigurations to a reasonable minimum.

By virtue of their experience, the telescope operators are aware of conditions which may reduce the quality of the data, and if requested they can make brief comments on the observing logs. One of these conditions is interference, especially at low frequencies. Another is weather. The operator has the responsibility of shutting down to protect the telescope in conditions of winds exceeding 25 mph or heavy snow or ice loads. At the operator's discretion, any procedure or activity which is felt to be unsafe for the telescope, equipment or personnel, or which threatens data collection, may be halted.

On the other hand, the telescope operators are not astronomers, and they are not mind readers. An observer should discuss any special concerns or requirements with the operator rather than assume that they will be attended to. The operator on duty will "pass the word" to the operator on the next shift. The operators are not computer programmers and are not expected to reduce data, although they do have some famillarity with pointing checks.

### 1.4. SCHEDULING

Telescope observing schedules are normally sent to observers one to three months in advance. Assigned times are determined on the basis of the observing requests of many scientists and a reasonably efficient use of telescope time.

Beyond normal weekly maintenance and holidays the only reasons for 300 foot telescope shutdown are equipment failure, power failure, winds exceeding 25 mph , and heavy snow or ice loads. At least one engineer is available at all times to correct equipment malfunctions. Pointing accuracy and efficiency tend to degrade as the wind and snow load limits are approached, and it is the operator's duty to maintain telescope safety and to shut down at his or her discretion.

### 1.5. OPERATING ROUTINE

A scan by scan observing $\log$ is kept by the telescope operator giving time and position information of the telescope for later reference by the observer. The observer gets a copy of all observing logs taken for the program, and if a limited amount of additional information is wanted on these logs, the operator should be told at the beginning of the session.

Unless otherwise instructed, the operator will send the magnetic data tape to Charlottesville each weekday morning around 0800. Logs are sent to the Green Bank Telescope Services Division Office (room 214 in the Jansky Lab), and analog monitor charts and other plots are set aside for the observer each day at the telescope. Tapes sent to Charlottesville are put into an archive library. The tape librarian will send periodic reminders of an observer's holdings, along with requests to release tapes of no further use.

## 2. TELESCOPE STRUCTURE

This chapter describes the limitations on observations imposed by the physical structure of the telescope itself, aside from the obvious limitations of a transit instrument.

### 2.1. PHYSICAL LIMITS

The primary indicated declination limits are nominally $+89^{\circ} 50^{\prime}$ and $-18^{\circ} 30^{\prime}$ but may vary by a few arcminutes depending on temperature. Indicated coordinates are those indicated by the position encoders on the telescope structure, but they are quite close to the actual position on the sky. Beyond these limits the telescope can be driven manually to back-up limits of $+91^{\circ} 04^{\prime}$ and $-19^{\circ} 30^{\prime}$ with the variable speed motor. When operating in card control mode, it should be remembered that these limits are indicated and a 1950 or true position may be beyond the limits after precession and/or pointing corrections are applied. If a primary limit will be encountered, the telescope will not move under computer control from the current position.

Tracking in right ascension is accomplished by moving the feed in the focal plane. There are two feed carriage systems. One is a 14 m , fixed focus east-west set of rails, called the travelling feed, used for frontends below 1 GHz . The other, called the Sterling mount, is a more accurate mount for radiometers above 1 GHz and is capable of focusing, rotation and east-west translation up to 45 cm on either side of the telescope axis.

Hour angle limits are $\pm 15$ inches or about $\pm 2^{m}$ sec $\delta$ around the telescope's meridian on the Sterling mount (used above 1 GHz ) and are $\pm 275$ inches or about $\pm 28^{\mathrm{m}}$ sec $\delta$ on the travelling feed carriage. Hour angle limits using the $300-1000 \mathrm{MHz}$ carriage on the travelling feed are $\pm 132$ inches (reference: Appendix D), allowing a total tracking time of about $33^{\mathrm{m}} \sec \delta$, but the feeds are offset from the center of the box making the tracking limits asymmetrical (see section 4.2.3). The limits in terms of time are very slightly dependent on frequency and aperture illumination as explained in the section on beam deflection factor. Here again it should be remembered that precession and pointing corrections will make these limits unsymmetric about the true or 1950 meridian.

### 2.2. DRIVE SYSTEM LIMITS

Two motors are used for declination drive. One provides continuously variable speeds from 0 to $2: 25 /$ minute ( 0 to $135^{\prime} / \mathrm{minute}$ ), and the slew motor has a fixed nominal speed of $10^{\circ} /$ minute.

A three second time delay is built into the declination drive system to allow for telescope deceleration before reversal of direction of travel or speed change. If the telescope position is dependent on a rate and start time with very close sequencing (e.g. in wobbles), this delay must be taken into account. A rule of thumb for slewing to a new
position is to add five seconds for deceleration and position trim to the time required to slew at $10^{\circ} / \mathrm{min}$. Additional time may also be required for receiver adjustments.

Maximum hour angle drive rates on the movable feed systems are 0.5 inches/sec (about $1^{\circ} / \mathrm{min}$ ) on the Sterling mount and 1.5 inches/sec (about $3^{\circ} / \mathrm{min}$ ) on the travelling feed carriage. Note that hour angle and right ascension rates are not the same due to the apparent motion of the sky.

The travelling feed system is fixed focus and fixed rotation angle. The Sterling mount allows rotation of the receiver box up to $\pm 200^{\circ}$ from indicated zero at a maximum rate of $13^{\circ}: 3 / \mathrm{sec}$, and a total focus travel of 1270 mm at a maximum rate of $6.76 \mathrm{~mm} / \mathrm{sec}$. Indicated zero on the focus travel is an arbitrary point and the actual in-focus position will depend on receiver box dimensions. Refer to receiver data sheets to determine the beam configuration at zero rotation angle. Positive rotation is in the direction from north through east on the sky.

### 2.3. PERTINENT HISTORY

The 300 foot structure and surface has undergone many changes which affect its pointing and efficiency. As a consequence, many very careful measurements of antenna parameters made in the past may no longer be appropriate. To help the observer determine the validity of a previous set of calibrations, a brief history of the telescope from the installation of the present surface is given in Table 2-1. It is safe to say that any calibrations made before 1 December 1970 should be disregarded except as a guide for performing new measurements. Some of these changes probably had little effect on the performance of the telescope, but their effects should not be discounted without at least spot checks.

TABLE 2-1

## A BRIEF HISTORY OF STRUCTURAL CHANGES

| Date | Change |
| :---: | :---: |
| 1 July - 7 Dec. 1970 | Installation of new surface. |
| 17 Sept. 1970 | Installation of cryogenic lines on feed support legs. |
| 16 Apri1 1971 | Installation of two 7/8" Heliax cables on south leg ( $0.5 \mathrm{lb} / \mathrm{ft} / \mathrm{cable}$ ). |
| 20 Apri1 1971 | Welding of north and south feed leg joints to remove pointing hysteresis. |
| 20-28 April 1971 | Installation of Sterling mount. |
| 24 June and 16 Sept. 1971 | Line of panels from south leg to north lip reinforced for walking. |
| 11-18 Nov. 1971 | Addition of counterweights: 3000 pounds at south box and 6022 pounds at counterweight box. |
| 26 Sept. 1972 | Alignment of travelling feed rails to remove twist. |
| 29 March 1973 | Welding of gusset supports. |
| 4 June - 29 July 1973 | Painting of entire structure. |
| 22 June 1973 | Welding of two broken gussets on bottom cord, south of east bearing. |
| 17 Jan. 1974 | Removed east declination encoder for repair. |
| 15 Feb .1974 | Installed interference monitor antenna above feed cabin. |
| 18 July 1974 | Reinstalled east declination encoder. |
| 19 Sept. 1974 | Removed west declination encoder for overhaul |
| 24 Oct. 1974 | Removed travelling feed assembly for repair and recabling. |
| 18 Dec. 1974 | Reinstalled travelling feed assembly. |
| 27 Feb. 1974 | Reinstalled west declination encoder. |

## 3. RECEIVERS AND FEEDS

### 3.1. RECEIVER CONFIGURATIONS

There are quite a few receiver configurations avallable at the 300 foot, so it is essential that the observer specify the type of observing intended and any special needs. The observing proposal often does not contain enough detail to guide the engineer in charge, so the observer should get in touch with the engineer to make any special requirements known, preferably 2 to 3 weeks before the program is to begin. Some parameters, such as bandwidth, can be easily changed in the control room while others, such as polarization or feed and switch configurations, may require major feed or cable changes in the front end box which require several hours to accomplish.

The telescope installation data sheet, or receiver set-up sheet, is a basic source of information about an observer's own set-up. This sheet is prepared by the engineer who installed the receiver, and is available at installation time. It contains vital information about the feed polarization, i.e. which polarization goes to which data channel, and focus distance. It also describes receiver parameters such as bandwidth, system temperatures, and noise tube temperatures. The LO multipliers, needed by the computer to set the sky frequency, are also found on this sheet. Particularly useful for returning observers are comments on major changes in the system.

### 3.2. FEED PERFORMANCE: ON AXIS

This section is intended to outline the instrumental parameters, effects, and corrections with which an observer should be concerned when planning and executing an observing program -- except for the important subject of pointing, which is discussed in a separate chapter. Where parameters such as aperture efficiency and beamwidth have been measured with a specific radiometer system, they are given herein. These parameters are more extensively determined for some telescope-radiometer combinations than others, depending on their purpose and the extent of feedback from previous observers. In any case, it is ultimately the observer's responsibility to insure that the proper parameters are being used, although the values given herein are the best that are currently available. It is important to remember that parameters such as pointing corrections and focus, done at a particular wavelength, are not usable for a different radiometer, even at the same wavelength; a different feed on the same radiometer will also produce different aperture and beam efficiencies. Even the declination dependence of aperture efficiency will, in general, be different for different feeds at the same frequency.

At many places in this chapter, procedures are given for measuring the parameters under discussion. It would be most helpful if each observer contributed any calibrations performed during a program or call attention to incorrect information that may have been received from NRAO.

For convenience, the discussion of feed performance has been divided into two parts: "On axis behavior" and "Off axis behavior." These titles refer to the declination and hour angle dependence, respectively, of the various telescope parameters. Tracking in right ascension is accomplished by moving the feed in the focal plane. A different set of effects is associated with beam motion in each direction.
3.2.1. APERTURE EFFICIENCY

The operational definition of aperture efficiency is given in equation (3-1).

$$
\begin{equation*}
\varepsilon_{A}=\frac{2 \mathrm{kT}_{\mathrm{A}}}{\mathrm{SA}} \tag{3-1}
\end{equation*}
$$

where $\mathrm{T}_{\mathrm{A}}$ is the measured antenna temperature produced by a point source of flux density $S$, in the peak of the beam, and $A$ is the geometrical area of the aperture ( $6567 \mathrm{~m}^{2}$ for the 300 foot). If S is in Jansky's and $T_{A}$ in Kelvins, then

$$
\begin{equation*}
\varepsilon_{A}=0.420 \mathrm{~T}_{\mathrm{A}} / \mathrm{S} \tag{3-2}
\end{equation*}
$$

The aperture efficiency is a function of illumination, polarization, losses in the feed, and dish deformations. The first three of these can be a strong function of frequency because of changes in VSWR and feed radiation pattern. Dish deformations have their greatest effect at short wavelengths, of course, but the detailed dependence of aperture efficiency on them depends on the phase and amplitude structure of the wavefront striking the surface from the feed (using reciprocity and considering the feed as a transmitter). For this reason each radiometer-feed-surface combination behaves differently as a function of declination at the same wavelength.

In many cases only the relative variation of aperture efficiency with declination is important, the measurement of which requires only that the secondary calibration source (noise tube or diode) remain steady during the measurements. Absolute determination of the aperture efficiency is much more difficult because both $T_{A}$ and $S$ must be known. $\mathrm{T}_{\mathrm{A}}$ is derived by comparison with an internal noise standard in the radiometer which can be measured in the lab to a few percent, at best, and at worst can be in error by over $25 \%$. The method of caldibration of the noise standard is important because it often varies with frequency. Therefore, a wideband noise standard value is not necessarily valid for narrow band spectral line work and vice versa.

The most reliable way to determine the aperture efficiency of the 300 foot is to do drift scans of as many sources as possible of known flux over as wide a declination range as needed for one's observations. Be careful not to choose variable sources or sources larger than a tenth of a beamwidth. Good references for radio source flux densities are Bridle et al., 1972 [47], Kellermann et al., 1969 [48], and Fomalont and Moffet 1971 [49]. A compilation of flux density calibrators is included
in Appendix $B$ to this manual. Remember that flux densities usually refer to a particular polarization angle at a particular frequency.

Properly calibrated drift scans may be obtained using the pulsed cal mode or the digital receiver. Otherwise, put a noise calibration on the record immediately before and after the source passes through the beam. A comparison of the peak source deflection to the noise calibration deflection will give the noise calibrator in flux units, which, if the noise calibrator is known in temperature units, can be used to find the aperture efficiency in equation (3-1). If the declination pointing corrections are not precisely known, drift scans at several declinations may be necessary or the peak deflection corrected assuming a beam shape once the pointing corrections are known. The on- off method of determining source deflections is difficult to use on the 300 foot because of the variation of aperture efficiency with hour angle when a source is tracked. Even if extensive calibrations have been made on a previous observing session, at least spot checks on the calibrations should be made every session.

To indicate the useful declination range of the 300 foot at several wavelengths, representative plots of aperture efficiency as a function of declination are given in Figure 3-1. Note the difference in curve shape for different feeds at 21 cm . All reports which are on file with the "Friend of the 300 foot" and which discuss any of the parameters in this chapter are referred to in the References. The various radiometers are too numerous to discuss individually and for some of them there is very little written information on their performance on the telescope. As more information becomes available for each radiometer, references will be added to the manual.

Recent investigations [53, 56] reveal lateral defocusing to be a primary cause of the shape of the curves in Figure 3-1. As the telescope deforms under the influence of gravity the new shape resembles a parabola with an axis slightly offset from the nominal axis. The focal point actually moves in the north-south direction away from the location of the feed, causing a loss of efficiency which is most severe at the higher frequencies.

### 3.2.2. BEAM EFFICIENCY

Beam efficiency is an often misunderstood term in observational radio astronomy. Consequently there are several definitions, each of which applies only in a very specific case.

In practice, beam efficiency, $\varepsilon_{B}$, is sometimes used to convert observed antenna temperature, $T_{A}$, into source brightness temperature, $T_{B}$, for an extended source. The strict relation between $T_{A}$ and $T_{B}$ is

$$
\begin{equation*}
T_{A}=\frac{\operatorname{enth}_{\text {source }} \mathrm{T}_{\mathrm{B}}(\theta, \phi) \mathrm{R}(\theta, \phi) \mathrm{d} \Omega}{\left\{\int_{\pi} \mathrm{R}(\theta, \phi) \mathrm{d} \Omega\right.} \tag{3-3}
\end{equation*}
$$

where $R(\theta, \phi)$ is the power response of the antenna in the direction ( $\theta, \phi$ ). Only if the source is of uniform brightness can an equation defining beam efficiency be written which contains only antenna parameters:

Even then the source extent appears in the integral limits. Thus, any definition of beam efficiency in terms of antenna parameters only is arbitrary and of little practical use except as a measure of antenna quality.

Two properties of the beam efficiency as defined by equation (3-4) are worth mentioning, however. First, the beam efficiency is usually greater than the aperture efficiency if the integral is over the main beam. Second, the beam efficiency varies more slowly with declination than does the aperture efficiency because power lost in the peak of the main beam generally goes into broadening the beam and into nearby sidelobes as the dish is deformed.

The exact procedure for treating extended source observations depends on the scientific objectives. If the total source flux density is the goal, one could either correct for beam response fall-off if the source is roughly a HPBW or less in extent (assuming one knows the source brightness distribution), or one can completely map the source. If the source area is mapped, the total flux is simply the integral under the source map divided by the normalized antenna beam integral. In this case the map intensities are expressed in "Jy per beam area" which in many cases is a much more useful physical unit than brightness temperature, and allows one to use the direct secondary noise source calibration in terms of point source flux density.

### 3.2.3. BEAM WIDTH AND BEAM SHAPE

Nominally the half-power beam width of the 300 foot in arcminutes is 0.5 times the wavelength in centimeters. It varies by as much as 15 or $20 \%$ from this (usually larger) depending on illumination taper and shadowing, declination, and to a certain extent on wavelength because of beam broadening at higher frequencies owing to surface irregularities. To a first approximation the one dimensional main beam shape is gaussian when the illumination taper is -15 db at the dish edge, as is the case with many NRAO feeds. However, the gaussian shape is a poor approximation above 1 GHz at extreme declination limits where the beam is decidedly asymmetrical, and at all frequencies when the feed is off axis, as will be discussed later. The north-south beam width is generally larger than the east-west beam width because of the feed support shadows [56].

Typical beam contour maps are given in Figure 3-2 at declinations of $+47^{\circ}$ and $-15^{\circ}$ for the cooled 21 cm receiver [4], and much deeper contours are shown in Figure 3-3 for the 21 cm four feed system [2].

Figure 3-4 is a plot of measured half-power beam widths for the four feed system. The declination effect on beam width is more pronounced at shorter wavelengths. Figures $3-2$ to $3-4$ are meant only to be representative, and each feed must be calibrated separately.

### 3.2.4. SIDELOBES AND SPILLOVER

The sidelobe structure will be a strong function of the feed illumination taper and surface irregularities. One feature which is always present is the east-west diffraction spike seen in Figure 3-3, which is caused by the feed supports. If the dish is heavily illuminated, Airy's rings will become apparent. These are normally suppressed by proper illumination taper. Sidelobes far from the main beam are typically 50 to 60 db down from the main beam and are the result of diffraction by sharp irregularities on the dish. Far sidelobe structure can be strongly frequency dependent; this could produce spectral baseline distortions when a strong source such as the sun is in those sidelobes.

Spillover, which is the power from the feed not intercepted by the dish, is roughly 60 db down from the main beam but subtends a large solid angle mainly in the direction of the 300 K ground. This can contribute 5 to 50 K to the total system temperature. The peak in the ground contribution to $T$ occurs when the antenna is near zenith position. Below 500 MHz , spillover can also pick up local power line and ignition interference.

### 3.2.5. FOCUS

Only the Sterling mount is capable of moving the feed parallel to the telescope axis. The travelling feed is a fixed distance from the dish and the placement of each feed with respect to the actual focal point is determined when the receiver front end is built. Only indirect checks, such as beam shape and sidelobe structure, can be made on the focus of receivers below 1 GHz . Even these checks are dependent on illumination and interactions with the feed support structure.

Two methods have been used to determine optimum focus for the 300 foot. The simplest, which has been successful at 21 cm , is to track a moderately strong source while quickly running the feed back and forth through the approximate focal plane. With appropriate position marks on the receiver output chart recording the peak efficiency point can be determined. For this method to work, one must know the pointing corrections accurately and stay within 2 or 3 beamwidths of transit, and the receiver baseline must not change due to dish reflections when the feed is moved in either focus or translation (tracking) when pointed at blank sky.

If the baseline variations are a problem in the above method, the alternative is to make drift scans of a number of sources, each at a different focal position. The relative source strengths usually are not known accurately enough to monitor the efficiency at the different focal
positions, but the HPBW is a weak function of focus. With at least 5 or 6 drift scans, the point of minimum HPBW can be determined with sufficient accuracy to set very close to optimum focus.

### 3.2.6. POLARIZATION

Precise polarization measurements are difficult with any radio telescope because of the myriad of instrumental effects. However, a number of successful polarization observations have been made with the 300 foot (e.g. [10], in which most of the instrumental effects have been accounted for). This manual does not claim to define the best way to measure polarization in each case, so only a brief mention of some of the instrumental problems will be given.

Point source and extended source measurements differ in that beam shape and sidelobes are more important in the latter. Hence, unpolarized sources used for calibration must be roughly the same angular size as the unknown source. If a dual polarized feed is used, there may be a pointing offset between the two beams. Or, if a single polarization feed is rotated, its beam axis may not be coincident with the axis of rotation. Spillover will be different for opposite polarizations in a dual polarization feed or for different position angles of a single feed. This will cause a differential variation in system temperature of two feeds as the antenna is moved in declination, or a baseline variation as the feed is rotated.

The phase and amplitude distribution of the illumination will also be different for the two polarizations in a dual feed and at different position angles in a single feed, owing to the intrinsic properties of the feed and to interactions with the feed support legs. The latter is especially important at low frequencies. Also, surface panel resonances may cause significant depolarization, particularly at low frequencies. Differences in illumination will produce different aperture efficiencies at different position angles and may cause the declination correction curve of aperture efficiency to be different at different position angles.

In an effort to provide a secondary polarization calibrator, three wideband antennas were installed at the apex of the 300 foot to radiate a polarized signal to the feed. Two antennas ( $400-1000 \mathrm{MHz}$ and $1-8 \mathrm{GHz}$ ) are fixed circularly polarized and the other ( $100-1000 \mathrm{MHz}$ ) is rotatable and linearly polarized. A great deal of caution must be exercised when using these antennas because of strong reflections from the feed support legs, particularly below 1 GHz . For example, in a couple of cases, between 250 and 500 MHz , the sense of circular polarization actually appeared to reverse when the feed was moved away from the feed supports. A comparison of the box rotation angle and calibration antenna angle, when the calibration signal is maximized, indicates that measurements of the position angle of linear polarization is probably good to 5 or $10^{\circ}$ in most cases. However, one cannot trust any amplitude information obtained with the apex calibration antennas.

### 3.3. FEED PERFORMANCE: OFF AXIS

All. of the on axis properties of the 300 foot apply when it is used in the tracking mode, but additional effects arising from off axis operation of a paraboloid must be taken into account. Comments on these additional effects are given below under section headings corresponding to those used in the on axis discussion. Most of the comments apply to multibeam systems where at least one of the beams is off axis. An NRAO internal report [11] treats many of the subjects in more detail.

### 3.3.1. APERTURE EFFICIENCY

Figure 3-5 shows the variation of aperture efficiency as a function of beam offset for two radiometers ( $250-500 \mathrm{MHz}$ and the cooled 21 cm ). Note that all of the low frequency measurements agree to within about $2 \%$ at all frequencies. The 21 cm points are systematically higher, and this may be due to a difference in illumination taper. Heavily tapered illumination will produce less relative fall off in aperture efficiency with feed offset than will more uniform illumination. Measurements have been made at 21 cm at widely different declinations, and little or no dependence of the shape of the curve in Figure 3-5 on declination is found.

The best method for measuring relative aperture efficiency as a function of hour angle is to track the right ascension of a reasonably strong source while scanning back and forth across the source in declination at a speed consistent with the antenna beamwidth. A source smaller than a tenth of a beamwidth should be used, and the antenna pointing corrections in right ascension and hour angle must be known accurately. If an absolute value of the aperture efficiency is to be obtained with the same series of scans, a noise calibration should be put on the record before and after the set of source scans. Measuring the aperture efficiency variation by continuously tracking a source is not advisable because of possible variations in the receiver baseline when the feed is moved in the focal plane.

Since the shape of the aperture efficiency versus beam offset curve depends on illumination, it should be measured for each separate feed when it is important. Note that if one is using the tracking feature of the 300 foot to increase sensitivity by integration, there is often little point in going beyond 5 HPBW, because even with proper weighting of the data very little increase in signal-to-noise ratio can be obtained with the addition of observations taken when the aperture efficfency is less than half its on axis value.

### 3.3.2. BEAM EFFICIENCY, BEAM WIDTH, AND BEAM SHAPE

The remarks under this heading in the previous section apply here with the additional complication that the beam efficiency changes while tracking a source. In equations (3-3) and (3-4), $R(\theta, \phi)$ would also be a function of time. Most of the power lost from the beam peak as the beam moves off axis goes into widening the beam (asymmetrically) and into the
coma sidelobe. Thus, the limits on the integrals in equations (3-3) and (3-4) are especially critical. Figure 3-6 shows an example of beam distortion when the beam is off axis. The contour levels do not go quite low enough to show a separate coma sidelobe in this diagram. This figure is intended to be illustrative only because the details of the beam distortion will depend on individual feed properties.

### 3.3.3. SIDELOBES

One important additional sidelobe, the coma lobe, appears when the beam is moved off axis. It is located approximately 1.6 beamwidths from the main beam along a vector from the main beam to the telescope axis, and its strength is strongly dependent on beam deflection and somewhat dependent on illumination taper. The coma lobe can be as high as $10 \%$ for displacements of 4 HPBW .

The near and far sidelobes associated with on-axis operation are still present with the deflected beam, but their detailed structure will change with beam motion.

### 3.4. BASELINES

In continuum observations the term baseline refers to the output of a radiometer when the source is not in the main beam. If we neglect receiver instabilities and interference, the main sources of baseline variation with the feed on-axis are changes in ground radiation pick-up with changing declination, and time-variations in atmospheric radiation at frequencies above about 2.5 GHz . The first is not a problem with right ascension drift scans. The second is a strong function of the amount of water vapor in the direction of the beam. In the case of small source work, beam switching can help cancel atmospheric contributions to baseline instabilities, but at times the small-scale structure of the water vapor distribution can be so pronounced as to make 6 cm observations difficult even when beam switching.

During the day, the presence of the sun in the telescope sidelobes can be a source of serious baseline problems. The sun is moving with respect to the sidelobes regardless of whether the telescope is motionless for a drift scan or tracking at the sidereal rate.

Spectral baselines, or variation of receiver output with frequency, in the true total power sense are mainly a product of the receiver bandpass characteristics. The gross frequency dependence of the receiver system can be taken out by subtracting a reference spectrum, taken with the antenna pointed off the source or with the receiver switched to a resistive load or to a different frequency from the source spectrum. A number of secondary effects then become evident in the baseline, and in general these effects are difficult to eliminate entirely.

When the reference is taken by moving the antenna, instabilities in the receiver bandpass, and strong sources such as the sun or ground radiation in the antenna sidelobes, can cause undulations in the
difference spectrum. Load or frequency switching can be done much more rapidly to eliminate effects of receiver bandpass drifts, but because the receiver front end characteristics will be considerably different at a different center frequency or when connected to a load, the baseline will still not be flat. Generally, if the total bandpass used is less than about 1 MHz , then load or frequency switching will produce acceptable baselines. Bandwidths above 1 MHz usually require operation in what is commonly called the total power mode, in which the reference spectrum is taken in a different part of the sky from the source. In this case one must be careful to take the reference spectrum with the feed in the same position(s) with respect to the dish (e.g., if a source is tracked, the reference point in the sky should be tracked over the same hour angles and roughly the same declinations) because of frequency dependent interactions of the feed and structure.

Some work on the 140 foot indicates that excess noise from either ground radiation or the sun can be scattered onto the dish surface and interfere with direct radiation into the feed. This interference is constructive or destructive depending on frequency and can be a source of spectral baseline ripples. Normally, ground radiation effects tend to cancel out in the total power mode at the 300 foot since the reference is usually taken at the same declination as the source observation. It is known, however, that the sun can cause baseline ripple with a characteristic length of 5 to 10 MHz and an amplitude at 21 cm of up to one Kelvin. No particular correlation of baseline ripple amplitude with solar hour angle has been established and many useful spectral line observations have been made during the day with a bandwidth of 10 MHz .

All of the above comments are intended only as guidelines because other observing considerations may be more important than baseline quality.

Figure 3-2. Beam shapes measured with the cooled 21 cm receiver feed on axis. Top figures are channel A with E vector north-south and lower figures are channel B with E vector east-west. Contours are at $-1,-3,-6,-9,-12$, and -15 db levels. Reference [4].

## 4. POINTING

Pointing the telescope to the proper position on the sky is one of the most basic aspects of observing. The subject of pointing has received a considerable amount of attention, and continues to be a major aspect of telescope maintenance. Still, observations that depend critically on accurate pointing require attention by the observers themselves. As for others, there are very few programs so short that there is not enough time for at least spot checks of the pointing.

The purpose of this section is to acquaint observers with those aspects of telescope pointing that require their attention, or at least their awareness, the terminology involved, and procedures for improving the pointing.

The first subsection describes the four coordinate frames that are computed and carried along with the data. In particular, the difference between "apparent" and "indicated" coordinates is essential to the understanding of the nature of "pointing corrections." The second subsection describes the mechanics behind the application of pointing corrections, and summarizes what is known about the pointing for various receiver/feed combinations. The moral of this subsection is that there is no single pointing correction for all receivers, and that at the very least, the observer must be certain to choose the appropriate correction. The third subsection describes methods to refine to pointing.

### 4.1. COORDINATE FRAMES OF REFERENCE

The telescope position may be commanded in a number of coordinate frames of reference. The H316 computer performs the computations necessary to convert from one frame to another. The four frames that are used are epoch, apparent or true, indicated, and galactic.

The epoch coordinate frame consists of positions in equatorial coordinates at a given epoch. The only epoch now available is 1950.0 .

The apparent coordinate frame consists of positions in equatorial coordinates at the epoch of the observations. The difference between epoch and apparent coordinates is precession, aberration, and nutation from 1950.0 to the epoch of the observations. Epoch and apparent coordinates are computed without any reference to the physical properties of the 300 foot telescope.

The indicated coordinate frame consists of positions as indicated by the position encoders on the telescope. Quite literally, the indicated coordinates are "what the dials read." The position encoders have been set so that indicated and apparent coordinates are nearly the same, but that is really a matter of convenience since indicated coordinates have no real astronomical meaning. But since the position encoders are part of the feedback loop for keeping the telescope at a commanded position, a position in any coordinate frame must finally be converted to a position in the indicated frame. Indicated coordinates are the "machine code" level instructions for telescope positioning.

The differences between apparent and indicated coordinates are due to slight misalignments in the telescope axes, encoder offset errors, and deformations of the telescope structure due to gravity and differential heating by the sun. Since these differences are small, the transformation from apparent to indicated coordinates is linear, as described in the next subsection. The pointing corrections are a functional fit to the differences between apparent and indicated coordinates, determined by measuring the indicated coordinates of sources with known positions.

The galactic coordinate frame consists of positions in new galactic coordinates. These coordinates are transformed to 1950.0 equatorial coordinates, and then treated as epoch coordinates. That is, they are precessed to the present epoch and pointing corrections are added.
4.2. POINTING CORRECTIONS.
4.2.1. POINTING CORRECTION EQUATIONS.

The pointing corrections are the difference between apparent and indicated positions. That is, they are the difference between the position that the astronomer wants to observe and the position indicated by the position encoders on the telescope. Since these differences are small, right ascension and declination corrections can be treated independently. The present method for implementing pointing corrections is to use standard equations in the H 316 computer for which coefficients can be entered via cards.

The right ascension pointing correction equation is

$$
\begin{equation*}
\Delta \alpha=m+n \tan (\delta)+c \sec (\delta) \tag{4-1}
\end{equation*}
$$

where $\delta$ is the indicated declination, and where $\Delta \alpha, m, n$, and $c$ are in seconds of time. This is the offset equation for a transit circle whose axis is displaced from true east-west and from the horizontal. The current values of $\mathrm{m}, \mathrm{n}$, and c are listed in Table 8-1, and are entered into the H316 computer on an "A" card (Section 8.1.1). This is the correction for observations on axis.

There is an additional correction for observations at non-zero hour angles, called the beam deflection factor (BDF). The BDF is the ratio of the angular displacement of the beam to the angular feed displacement [11]. The value of the BDF depends on the feed in use, but is usually between 0.84 and 0.875 . However, beyond some critical hour angle the BDF increases in the sense that the feed need not be moved as far to obtain a given beam deflection. For the traveling feed, this critical angle was measured to be $3: 15$ at 400 MHz by Greenhalgh [9], and a more recent measurement by Guiffrida and Haschick [32] indicates that this critical angle scales inversely with frequency (see [53]). Values of the BDF, critical angle, and additional BDF, for the travelling feed and for the Sterling mount, are entered into the H316 on a "T" card, as described in Chaptef5. It is necessary to calculate the additional BDF as a fraction of $2^{( }$for entry into the computer. A specific example, taken from [9], is shown in Figure 4-1.

The declination pointing correction equation is more complex because the dish deformations are not easily modeled. The equation is

$$
\begin{equation*}
\Delta \delta=C_{0}+C_{1} \delta+C_{2} \delta^{2}+C_{3} \delta^{3}-\Delta L \tag{4-2}
\end{equation*}
$$

where $\Delta \delta$ is in arc seconds, $C_{0}, C_{1}, C_{2}$, and $C_{3}$ are the pointing coefficients for a particular combination of receiver and feed, and $\Delta L$ is the level curve correction, described below. Particular sets of declination pointing coefficients are stored in the H316 computer and are identified by a two character identifier. The most recently determined coefficients are given in Table 8-1, and the identifiers are listed in Table 8-3. Ask the "Friend" about more recent updates to the pointing coefficients. The declination pointing coefficients are entered via a "D" card (Section 8.1.2).

### 4.2.2. ELECTRONIC LEVEL CURVE CORRECTION

In August 1979 an electronic level was installed on the east tower of the telescope to investigate the effect of differential heating by the sun. The level is a pendulum type electronic level, designed to be read remotely by computer. The level is mounted directly over the declination position encoder on the east tower. The level reads the tower til.t in the north-south direction only. In April 1980, the electronic level was incorporated into the feedback loop which keeps the telescope on position. It was found that the sun was causing a bending of the support structure which was directly reflected in the pointing. However, the telescope is not perfectly balanced, and so there is an unavoidable bending of the support structure as the telescope is moved. The level curve is this nominal relationship between the electronic level reading and the indicated declination, which is best measured on windless nights, preferably several hours after sunset to give the structure time to equilibrate thermally. This level curve is already incorporated into the nominal declination pointing curves described above, so the bending due to solar heating is the difference between the electronic level reading and the level curve. This difference is the level correction.

The level output is sampled every 0.2 seconds and averaged for 10 seconds. The nominal level curve is represented by a cubic polynomial in the indicated declination so that the level correction is:

$$
\begin{equation*}
\Delta L=\bar{L}-\left(L_{0}+L_{1} \delta+L_{2} \delta^{2}+L_{3} \delta^{3}\right) \tag{4-3}
\end{equation*}
$$

where $\Delta \mathrm{L}$ is in arcseconds, $\delta$ is the indicated declination, $\overline{\mathrm{L}}$ is the ten second average level reading, and $L_{0}, L_{1}, L_{2}$, and $L_{3}$ are the nominal level curve coefficients. The current values of the level curve coefficients are listed in Table 8-1, and are entered into the H316 via an "L" card (Section 8.1.3). A positive level correction is in the sense of a northward tilt, and so the level correction is subtracted from the declination correction.

The console has a toggle switch which can be used to disable the level correction in case of malfunction or windy conditions. The
telescope operator has control of this function. The H316 program checks the switch and prints a message on the CRT screen if the level correction is disabled.

### 4.2.3. TRAVELLING FEED RECEIVER OFFSETS

The travelling feed box ( $0.3-1 \mathrm{GHz}$ ) allows two feeds to be installed for observations at $300-500 \mathrm{MHz}$ or $500-700 \mathrm{MHz}$, and $700-1000 \mathrm{MHz}$. The two feeds are physically offset from center by $\pm 34$ inches, so that the whole box must be moved to get either feed on axis. The $300-700 \mathrm{MHz}$ receiver is located East on the box ( -34 inches), and the $700-1000 \mathrm{MHz}$ receiver is located West on the box ( +34 inches). These offsets are entered on a "B" card in the observer's setup deck for the DDP116 computer, which passes the value to the H316.

The effect of the box offsets on the hour angle limits of this receiver is discussed in Appendix D. The point to remember is that for a tracking scan the source peaks up at the box offset. For example, the two low frequency feeds peak up at -34 inches of travel. This means that a source can be tracked for less time before transit and more time after transit. The 98 inches of travel before transit correspond to $12^{\mathrm{m}} 20^{\mathrm{s}} \mathrm{sec} \delta$ of right ascension, and the 166 inches of travel after transit correspond to $20^{\mathrm{m}_{55} \mathrm{~s}} \mathrm{sec} \delta$. The calculations for the high frequency side of this receiver give the reverse answers. It is advisable to calculate these maximum offsets in beamwidths, heeding the advice of section 3.3 .1 that there is little to be gained by tracking more than 5 HPBW's off axis, due to the loss of aperture efficiency.

### 4.3. REFINING THE POINTING

### 4.3.1. DETERMINING THE PVALS

If an observer is willing to devote a significant amount of time to pointing correction measurements, or if such measurements are derivable from one's observations, then new pointing coefficients can be derived. Programs which run on the IBM in Charlottesville are available for obtaining least-squares solutions for the pointing coefficients. However, if the observer is satisfied with the nominal coefficients that are available, then simple corrections can be applied quite easily to account for small feed offsets. Three correction terms, which are called PVALS at the 140 foot telescope, correct for a declination offset and for right ascension dial error and box offset. The corrections, $P_{1}$, $\mathrm{P}_{2}$, and $\mathrm{P}_{3}$, in minutes of arc enter the pointing correction equations as:

$$
\begin{align*}
& \Delta \alpha=\left(m+P_{2} / 4\right)+n \tan (\delta)+\left(c+P_{1} / 4\right) \sec (\delta) \\
& \Delta \delta=\left(C_{0}+60 P_{3}\right)+C_{1} \delta+C_{2} \delta^{2}+C_{3} \delta^{3}-\Delta L \tag{4-4}
\end{align*}
$$

In principle, $P_{1}$ and $P_{3}$ could be determined from the measurement of a single source if $P_{2}^{1}$ were assumed to be zero. However, the separation of right ascension box offset and dial error requires at least one pair
of sources at widely separated declinations. If $N$ pairs of sources are measured, the solutions for the pointing offsets are:

$$
\begin{align*}
& P_{1}=\frac{1}{N} \sum_{m-1}^{N} \frac{\left(\Delta \alpha_{1}-\Delta \alpha_{2}\right)_{m}}{\left(\sec \delta_{1}-\sec \delta_{2}\right)_{m}}  \tag{4-5}\\
& P_{2}=\frac{1}{N} \sum_{m-1}^{N} \frac{\left(\Delta \alpha_{1} \sec \delta_{2}-\Delta \alpha_{2} \sec \delta_{1}\right)_{m}}{\left(\sec \delta_{2}-\sec \delta_{1}\right)_{m}}  \tag{4-6}\\
& P_{3}=\frac{1}{2 N} \sum_{m-1}^{N}(\Delta \delta)_{m} \tag{4-7}
\end{align*}
$$

where subscripts 1 and 2 refer to the two measurements within a pair. There is a function in the POPS/CONDAR analysis programs for computing the PVALS. This function does not use equations (4-5) through (4-7), but instead performs a least-squares fit. The function is known as PVALS, and is literally a carry-over from the 140 foot analysis system. In particular, it asks for input as if it were possible to measure declination and right ascension offsets simultaneously, which is generally not the case on the 300 foot. Since $P_{3}$ is simply the average of all the declination offsets measured in a set of observations, it is perhaps more easily calculated by hand than by typing the numbers into the PVALS routine. In that case, the PVALS routine can be used to simplify the calculation of $P_{1}$ and $P_{2}$, inputting zero for the declination offsets.

### 4.3.2. MAKING POINTING MEASUREMENTS

The previous section described the calculation of corrections to the pointing derived from a set of pointing observations. This section describes in general terms the procedures for determining the pointing offsets.

If possible, a good place to start when refining the pointing is to measure the constant term in the nominal level curve. A long series of observations has shown that the shape of the level curve is stable, but that the zero point tends to change. It is not known whether the nature of this change is a slow drift or occasional jumps, but the change has been monotonic over a period of about two years. The simplest procedure for measuring the constant term is to command the telescope to declination zero and read the level. However, as described in the section on the electronic level, these measurements can only be made during the proper conditions, when the structure is in thermal equilibrium and there is no wind. If these conditions cannot be met, then the zero offset of the level reading must simply be corrected for by the declination correction $P_{3}$. An averaged level reading is passed to the MODCOMP analysis computer with all continuum scans, so it is not always necessary to read the meter.

#### Abstract

The right ascension and declination pointing offsets must be measured by drift scans and declination scans, respectively. The telescope operators know how to obtain and reduce these data to obtain the pointing offsets. The Friend has source card decks for making pointing observations, or observations can be run in a manual mode making use of the source lists in Appendix B. From experience, the most straightforward method of determing pointing corrections for a single feed are drift scans for $\Delta \alpha$ and at least two declination scans for $\Delta \delta$. The scans can be reduced in a straightforward manner on the MODCOMP. However, if the data are reduced from a chart recording, one must be very careful to allow for marker pen offsets and distortions due to receiver time constants. In either case, these effects can be canceled out in determining $\Delta \delta$ by taking an equal number of scans in either direction while tracking the sources in right ascension. Be careful not to allow the feed to get so far off axis that the curvature of the sky changes the apparent source declination as measured by the 300 foot.

If two or more offset feeds are available, such as on the 21 cm four feed or the 11 cm three feed systems, a fairly good measurement of $\Delta \delta$ can be made with a drift scan by measuring the relative responses of two or three of the beams to the source when they are spaced approximately half of a HPBW in declination. Such spacing can always be achieved by rotating the box to the appropriate position angle. This method assumes that the beam offsets and relative efficiencies are well known.

A third method which has proven successful at 21 cm is to track a pointing calibration source and move off to half power beam positions in the cardinal directions. If the response is not equal in opposite directions, the pointing offset can be computed. This method may be applicable to other frequencies as long as baselines do not vary with feed position and enough tracking time is available to complete the sequence. Because of the variation of aperture efficiency with hour angle, opposing offsets must be measured at equal distances from and not more than about three beamwidths from transit. When done from card control, this method offers the advantage of checking the entire sequence of telescope control as is used in actual observing.

Good references for accurate source positions are Bridle et al., 1972 [47], Fomalont and Moffet 1971 [49], and the VLA calibrator list. Appendix $B$ consists of a calibrator source list and flux density list, furnished by P.C. Crane.

Observers who will be tracking their sources in right ascension may wish to measure the beam deflection factor (BDF), particularly if they wish to track sources at hour angles greater than 6 half-power beamwidths. The BDF can be measured fairly quickly by scanning the beam back and forth in right ascension across a reasonably strong source while recording the LST (and hence source hour angle, h), linear displacement of the feed, $L$, and receiver response on a chart recorder. From this record the angular feed displacement (L/focal length) and the beam deflection ( $h \cos \delta$ ) for each source-crossing peak can then be determined, and the slope of the line defined by these points is the BDF. To the accuracy of measurement all determinations of the BDF have
shown a linear relationship between $L$ and $h$ out to about 6 beamwidths, but at a critical distance of $3: 15$ on the travelling feed at 400 MHz the slope changes abruptly from 0.854 to 0.868 [9]. A value of 0.856 has been recently determined for the cooled 21 cm receiver [4][54][55]. These values agree quite well with a value of 0.85 calculated for a -18 db illumination taper on the 300 foot [11]. The critical angle appears to scale with wavelength [32][55], so if beam displacements of more than 6 HPBW 's are to be used, the critical angle and additional BDF will have to be determined at the frequency of interest.

SOURCE $\delta=33^{\circ}$
ASSUMED BDF $=0.84$ AS FIRST APPROX!MATION

1. CENTRAL BDF $=0.84\left(1+\frac{45^{\mathrm{s}}}{45^{\mathrm{m}} \times 60}\right)=\underline{0.854}$
2. CRITICAL DISTANCE $=15^{\mathrm{m}} \operatorname{COS} 33^{\circ}=3.15^{\circ}$
3. ADDITIONAL BDF $=\frac{220^{5}}{30^{m} \times 60}=0.12222$

ENTER AS FRACTION OF $2^{15}$
$0.12222 \times 2^{15}=\underline{4004,9}$

## 5. IF SECTION AND DETECTORS

This chapter describes some of the components of the observing system that determine the frequency band to which a receiver is tuned, and which bring the information in that band to the point where it is digitized. The Universal Local Oscillator (ULO) is a variable frequency synthesizer which can be computer controlled. The ULO is the basic frequency determining element in the system, since it generates the frequency signal which is mixed with the sky frequency signal to produce the intermediate frequency (IF) signal. The IF processor is a four channel device for mixing IF frequencies covering the wide range available from different receivers to the standard IF of 30 MHz used by the Model III autocorrelator plus a second output at 150 MHz .

The digitization of spectral line information is performed by the autocorrelator, which is the subject of Chapter 6. Continuum observations intended to calibrate line observations are also best performed using autocorrelator detectors. The process of digitizing the total power within the observed band for continuum observations is performed by square law detectors and analog to digital (A/D) converters. There are a number of parallel systems for accomplishing this. The "standard" continuum receiver consists of square law and synchronous detectors (among other things) whose output is fed into a network of A/D converters read directly by the DDP116 computer. The digital continuum receiver (DCR) is built around a powerful HP calculator which can digitize the output of internal or external square law detectors and then process those numbers to obtain a sophisticated variety of output data which is passed directly to the DDP116 computer. The variable bandwidth receiver contains a variety of bandpass filters in each of four channels, which allows the observed bandwidth to be changed easily. The square law detectors in this receiver have a very short rise time which allows fast sampling for pulsar observations. The 40 channel receiver is a filter bank of 1 MHz filters (measured at the 1 db points) separated in frequency by 1 MHz . This receiver has been used in a pulsar search.

The items discussed in this chapter are parts of the setup routinely handled by the engineer in charge of installation. Many observers have made successful observations without giving a moment's thought to the IF processor or square law detectors. This is not an advertisement to skip ahead to the next chapter -- quite the opposite, it is a warning that the documentation on a number of these items is rather thin, since most observers use them in standard modes. The documentation for the variable bandwidth receiver, in particular, seems to exist only as an oral tradition passed among pulsar observers. On the other hand, the digital continuum receiver is documented in a manual of its own, so that all of the items in this chapter consist of very brief descriptions.

### 5.1. UNIVERSAL LOCAL OSCILLATOR

The Universal Local Oscillator is a variable frequency synthesizer which generates the frequency used to mix from the sky frequency down to the intermediate frequency. Except for receivers for 300 MHz and below, the IF, rather than the sky frequency, is sent down from the front end
to the control room. The ULO is therefore the primary frequency determining element in the system. The ULO can be commanded by computer to set three frequencies, $F_{0}, F_{1}$, and $F_{2}$. The ULO usually stays on $F_{0}$, for total power or continuum observations, or, for frequency switched observations, switches in the pattern $F_{0}, F_{1}, F_{0}, F_{2}$, commanded by a signal/reference pulse from the autocorrelator. The ULO can also be used in a manual mode, where all three frequencies and the choice of which is used can be set from the front panel.

The primary frequency generated in the ULO, $F_{0}$ in hardware or L1 in software, is in the range $250-500 \mathrm{MHz}$. A frequency quadrupler is incorporated into the ULO so that the output frequency is in the range $1.0-1.99999 \mathrm{GHz}$. The frequency multiplier $M$ that must be specified in the setup cards for the spectral line programs (Chapter 9) is therefore usually 4 , except that there is a secondary output for which the multiplier is one.

An integral part of the ULO is a frequency counter, which monitors the primary frequency. These measured frequencies are passed back to the DDP116 computer for comparison with the commanded frequencies and the previous measurement. If the computer detects a discrepancy beyond a certain tolerance, an error message will be printed on the DDP116 teletype. The tolerance of these checks is $\pm 100 \mathrm{~Hz}$. An error does not halt the data taking. The ULO error messages and their meanings can be found in Table 9-5. If observations are made with the ULO in the manual mode, then the measured frequency passed back to the DDP116 is saved in the tape header with the data. The accuracy of this frequency measurement is also $\pm 100 \mathrm{~Hz}$.

### 5.2. IF PROCESSOR

The IF processor is a four channel mixer for converting an IF signal with a bandpass centered on frequencies in the range $50-500 \mathrm{MHz}$ to a center frequency of 30 MHz , which is required by the autocorrelator. The IF center frequency is entered manually on the front panel. Each of the four IF channels, identified as A-D, can be set independently to a different frequency. If only two IF signals are present, processors $\mathbb{A}$ and $\underline{C}$ must be set. The maximum bandwidth of the output of the IF processor is 20 MHz , more than enough for the widest bandwidth available in the autocorrelator.

As with the ULO, the IF processor has a built-in frequency counter. The output of this counter should be the IF center frequency dialed in on the front panel. The counter switches between the four IF processors, returning four frequencies to the DDP116 computer. The computer makes a comparison between the measured IF frequency and that specified by the observer. A discrepancy results in a ULO error (Table 9-5). Actually, only IF channels $A$ and $C$ are checked by the computer. The accuracy of these checks is $\pm 300 \mathrm{~Hz}$.

For continuum observations, secondary outputs from the IF processor are available with wider bandwidths and a center frequency of 150 MHz . These secondary outputs have been used, for example, as input to the
filter bank. In this connection it should be noted that four separate frequency synthesizers are used for the four channels, and so there is no phase coherence between the four output signals. Therefore it cannot be used with the IF polarimeter unless internal cabling is rearranged so that one frequency synthesizer drives both IF channels.

### 5.3. STANDARD CONTINUUM RECEIVER

The standard continuum receiver consists of amplifiers and square law detectors which operate at input frequencies of $5-300 \mathrm{MHz}$. The word "standard" should be taken simply to mean "analog", to distinguish it from the digital continuum receiver, just as those time pieces once thought of as standard must now be called "analog" watches. It is quite likely that the newer and more powerful digital continuum receiver will become the standard continuum receiver.

The analog outputs of the square law detectors, proportional to the total power , and/or analog outputs of synchronous detectors, proportional to the switched power in the observed bands, are fed into a multiplexed system of A/D converters which are sampled by the DDP116 computer. All the computer needs to know is the identifying number of the first A/D converter to sample, and the total number of data channels present. The computer assumes that the other data channels are on those A/D's which immediately follow that of the first channel. For example, if four receivers are in use with the first going to A/D number 8, then the other receivers are assumed to be on $A / D^{\prime}$ s 9,10 , and 11. All other aspects of the setup of this receiver are quite well standardized, and are set by the installing engineer.

The gain of the receiver is set according to the full scale temperature, which is that antenna temperature which will saturate the receiver. Adjustment of the full scale temperature during the course of an observing program to allow observations of very strong continuum sources is a routine procedure for the telescope operators, if a new full scale temperature is suggested by the observer.

### 5.4. DIGITAL CONTINUUM RECEIVER

The digital continuum receiver (DCR) is a receiver built around a powerful Hewlett-Packard calculator. The DCR is described in a separate manual [57], and so only a general description will be given here. This system is a post-detection synchronous demodulator which can operate at switch rates of up to 500 Hz and can provide a variety of switching combinations, such as load or beam switching with or without calibration and noise adding radiometry. This receiver continuously computes the system temperature, receiver gain, and rms output noise. Any of these functions can be transmitted to the DDP116 computer along with, or instead of, the detected signal. The receiver contains amplifiers and square law detectors designed to operate at an input frequencies of $5-500 \mathrm{MHz}$, with provisions for total power inputs from external square law detectors. In either case, total power voltages are fed to voltage
controlled oscillators (VCO's) followed by counters, to perform the analog to digital conversion. The calculator reads the counters, and applies an internally determined calibration factor, so that calibrated data in digital form are transmitted to the DDP116 computer.

There are many observing parameters which need to be set in the receiver's calculator. The calculator cannot read these parameters from the setup cards read into the DDP116 computer. One of these parameters is the full scale temperature to the computer, the antenna temperature at which data sent to the computer is saturated. As with the standard continuum receiver, adjustment of the full scale temperature to accommodate strong sources is an adjustment that can be made routinely by the telescope operator, if a new full scale temperature is suggested by the observer. It takes somewhat longer to adjust the full scale temperature on the DCR than it does on the standard receiver, about one minute.

### 5.5. VARIABLE BANDWIDTH RECEIVER

There are two primary distinctions between the variable bandwidth receiver and the standard analog receiver. These are (1) that it is easier to change bandwidths among those that are available, and (2) that the square law detectors have a very short rise time for fast sampling. This second feature makes this receiver the standard pulsar receiver. Bandwidths can be switched at the front panel to bandwidths of 10 kHz to 10 MHz in a 1,3 , 10 progression. Sample times down to 1 millisecond have been used in pulsar observations.

### 5.6. FABRI-TEK SIGNAL AVERAGER

The Fabri-Tek signal averager is a digital detector for periodic signals, primarily used for pulsar observations. The signal averager can be configured to sample 1, 2 or 4 input signals. The incoming signal is digitized at a rate which can be specified to a high precision, and successive samples are routed sequentially to the accumulator channels. After the last accumulator, the next sample goes back to the first accumulator for another sweep across the channels. The number of sweeps can be specified as a power of 2 , up to 32 K , or 32768 . The current integration can be viewed on a storage oscilloscope incorporated into the averager. At the end of an integration data taking stops so that the data can be read out to the computer. Data taking resumes after the data have been read out, without regard to the phase of the previous integration. This means that each integration begins at a different phase of a pulsar pulse, for example. The analog to digital conversion has a precision of 9 bits, and the accumulated data are read out as 16 bits.

### 5.7. IMPULSIVE NOISE BLANKER

A special purpose device available for continuum observations is an impulsive noise blanker. This is a device designed to remove automobile ignition, aircraft, and similar impulsive interfering signals from
continuum observations, and has been found to be quite effective for this purpose [58].

### 5.8. 40 CHANNEL RECEIVER

The 40 channel receiver is a bank of 40 filters. Each filter has a 1 MHz bandwidth between 1 db points, and the filters are separated in frequency by 1 MHz . There is a separate square law detector for each filter. This receiver has been used for a pulsar search by combining various filter outputs to reduce the total number of outputs to eight. These outputs are then fed into the multiplexed A/D converters which are sampled by the DDP116 computer. Aside from the pulsar search group's own programs there is no software support for data obtained with this receiver. This filter bank was at one time used as a spectral line receiver, but support for that function was discontinued long ago.

## 6. AUTOCORRELATOR

This discussion of the Model III correlation receiver is taken primarily from Electronics Division Internal Report No. 125, Correlation Receiver Model III: Operational Description, by A.M. Shalloway, R. Mauzy, and J. Greenhalgh, with an addendum by B. Vance [31].

### 6.1. SYSTEM DESCRIPTION

The receiving system described here is the equivalent of a multichannel spectrum analyzer, and measures the power spectrum over a selected bandwidth and center frequency. It does this indirectly by first producing a one-bit autocorrelation function of the selected signal. The autocorrelation function is Fourier transformed by the on-line DDP116 computer to produce the power spectrum. The theory of digital autocorrelation receivers and a description of an early receiver are available in the literature [7].

The correlation receiver contains an IF-Filter System, an analog to digital (A/D) system, and a digital correlation system. The IF-filter system filters out a selected bandpass and heterodynes it to the video frequency range, i.e. so that one side of the bandpass is at zero frequency. This signal is clipped to provide a rectangular waveform of fixed amplitude. The only correspondence between the clipped and unclipped signal is their zero crossing points.

The clipped signal is then fed into the digital system where it is sampled at a frequency equal to twice the bandwidth. The output of the sampler is called a "one-bit" sample. It indicates only whether the signal is positive or negative. The digital system is a high speed special purpose computer which uses the sampled data to produce 384 point, 192 point, or 96 point one-bit autocorrelation and crosscorrelation functions.

The correlation function is the result of an integration for a selected period of time (normally 10 seconds), as chosen by the observer. The integrated function is stored in a core memory until called for by the on-line DDP116 computer, and then the correlator starts another integration process for the next period of time.

In the process of clipping, amplitude information is 10st. To recover the amplitude information, the unclipped bandpass signal is square-law detected, smoothed, and converted to a train of pulses by a voltage to frequency converter. Counters connected to the frequency converter outputs produce a count which is proportional to the total power in the received signal. These data are also sent to the on-line computer.

The on-1ine computer applies a clipping correction and performs an inverse Fourier transform to generate a power spectrum. The computer data are available as an on-line graph by means of a storage oscilloscope and as an output to magnetic tape and the on-line analysis computer (MODCOMP).

The operation of this system as a radio astronomy receiver can be similar to that of a continum Dicke switched receiver. The receiver is continually switched between the signal to be observed and a reference signal. In the case of the correlation receiver, the two sets of data obtained are handled separately until it reaches the computer, at which point the reference may be added to or subtracted from the signal.

### 6.2. CONFIGURATIONS, BANDWIDTH, AND RESOLUTION

The autocorrelator has a total of 384 channels. These channels may be allocated to up to four receivers in four modes: (1) one receiver of 384 channels, (2) two receivers of 192 channels each, (3) two receivers of 96 channels each and one receiver with 192 channels, and (4) four receivers of 96 channels each. There are nine bandwidths available, ranging from 39.0625 kHz to 10 MHz in octave steps. The bandwidth of each receiver may be set independently.

The output spectrum produced by the on-1ine computer consists of computed points spaced df apart over a total bandwidth B. Each point represents the power within a filter having approximately a sin $x / x$ shape with a half-power width $W=1.21 \mathrm{df}$, and a spacing between nulls of $2 d f$. The relation between bandwidth, resolution, spacing and rms noise fluctuation, $\Delta T$, is

$$
\begin{array}{ll}
\mathrm{df}=\mathrm{B} / \mathrm{N} & \mathrm{~W}=1.21 \mathrm{~B} / \mathrm{N} \\
\Delta \mathrm{~T}=\frac{3.06 \mathrm{~T}}{\sqrt{\tau \mathrm{df}}} & \tag{6-2}
\end{array}
$$

where $N$ is the number of channels (i.e., 384,192 , or 96 ), $T$ is the system noise temperature, and $\tau$ is the integration time. Hanning smoothing the resulting spectrum results in a half-power width of $2 d f$.

Equation 6-2 assumes that half of the observing time is spent on the signal spectrum and half is spent on the reference spectrum. This is the usual mode of observing since the $50 / 50$ duty cycle gives the best sensitivity in the final spectrum. However, the correlator can run in a mode with a $90 / 10$ duty cycle to improve the sensitivity in the signal spectrum -- the numerical constant in equation 6-2 is reduced to 1.63 -but this advantage is lost unless at least nine reference spectra can be averaged together to obtain a comparable sensitivity. This is sometimes done in mapping programs. Current GaAsFET receivers are sufficiently stable for this scheme to work. The $90 / 10$ duty cycle can only be used in switched power programs, but then the reference spectra cannot be obtained separately on the on-line analysis computer. Only the switched spectrum for each scan is available on-line, so the data must be reduced off-line. In the total power mode, signal and reference data (within the same scan) are simply added together to yield a single spectrum, so the $50 / 50$ duty cycle must be used to give the proper weight to each portion of the data.

At the edges of a measured spectrum the rms fluctuation increases due to the attenuation at the edges of the band restriction filter in the correlator IF section. At the 6 db attenuation point the rms fluctuation doubles and data points beyond the 6 db level should be ignored. Approximately $7 \%$ of the spectrum should be dropped at each end, i.e. 25 channels out of 384,12 channels out of 192 , and 6 channels out of 96 at each end.

### 6.3. IF FILTER SYSTEM

The IF filter system may receive from one to four IF signals from the front-end box, provide filtering to establish the desired bandwidth, convert them to a lower frequency and clip the signals in preparation for digital processing. Other functions such as level control, gain modulation, total power detection, synchronous detection and voltage-to-frequency conversion are also included.

In each receiver, the input signal is filtered at 30 MHz and then converted to a lower frequency for the output of the next filter. The reason for the successive lowering of the frequency is to permit the final bandwidth determining filter to operate at the center frequency where its design will produce maximum cut-off slope. The filters are designed to have a sharp cutoff at the high end to minimize the aliasing of strong lines just beyond the band edge into the band. Each conversion causes the observed band of frequencies to be inverted, i.e., the internal mixers use the lower sideband. Low gain amplifiers are used between mixers and filters to correct for filter insertion losses, power loss due to bandwidth reduction and to provide an accurate source and load impedance for the filters. Diode switches are used for selecting filters and other signal paths because of their small size and low power drain.

The main signal output is a spectrum located between zero and a frequency equal to the bandwidth selected. This signal is fed to a clipper and then to the digital section for sampling and correlating. A parallel signal path through a square law detector and voltage-to-frequency converter provides an output frequency proportional to total power for counting and calibration in the digital system. The digital system furnishes switching signals to the filter system to operate the gain modulators, synchronous detectors, and test signals to the clippers.

### 6.4. DIGITAL UNIT

The clipper output, which is a rectangular waveform containing the frequency information of the original received signal, is sampled at a rate equal to twice the filter bandwidth (the Nyquist frequency). The sampled data are continuously stored at the end of a shift register of the appropriate length for each receiver. Each shift register feeds a one bit multiplier. The other input to the multiplier is the most recent data sample. A counter for each multiplier counts the number of correlations (both inputs positive or both inputs negative). Signal and
reference counts are integrated separately. The core memory contains the following data: signal correlation function, reference correlation function, power counters, and control words. At the end of a "dump time", typically 10 seconds, an interrupt is sent to the computer and the computer can begin transferring the data.

At the beginning of a scan the correlator is synchronized to the computer by a pulse from the computer. Due to timing restrictions with interrupts from the on-line computer and data taking modes, some precautions are necessary when setting up an observing program. The two precautions that observers should be aware of are: allow at least one dump time between the end of one scan and the start of the next, and make the scan length be one second longer than a multiple of the integration period to insure that the data from the last integration are recorded on tape. A rule of thumb would be to allow at least 17 seconds between the end of one scan and the start of the next, and to keep successive start times from being on the same second modulo the integration time. This rule of thumb is repeated with emphasis in Section 8.2.3, where the procedure for preparing an observing card deck is given.

### 6.5. COMPUTER PROCESSING

There are two levels of computer processing to be discussed. The first is that of recovering properly scaled spectra from the normalized autocorrelation functions, and the second is that of the differencing schemes used to improve baselines.

The data received by the on-1ine DDP 116 computer is processed in four major steps: (1) the one-bit autocorrelation function is normalized so that the value of the zero delay channel is one, and long delay channels tend to zero, (2) a correction for clipping (the van Vleck correction) is applied to each channel, (3) the corrected values are Fourier transformed, and (4) the spectrum is flipped end-for-end, if necessary, to correct for band reversals in the IF section. Data for each receiver are handled separately. The Fourier transform used has the property that the center of the band is in channel $\mathrm{N} / 2+1$, where N is the number of channels for that receiver.

The spectra are converted to temperature units by multiplying by the system temperature. The appropriate system temperature is the sum of receiver noise temperature, antenna signal temperature, and $\frac{1}{2}$ the calibration noise source temperature, all averaged over the receiver bandwidth. This quantity can be computed by comparing the total power counters with the calibration noise source on and off, and knowing the calibration noise source in temperature units:

$$
\begin{equation*}
T_{\text {sys }}=\frac{P_{\text {on }}+P_{\text {off }}}{2\left(P_{\text {on }}-P_{\text {off }}\right)} T_{\text {NS }} \tag{6-3}
\end{equation*}
$$

where $T_{N S}$ is the calibration noise source excess temperature.

A differencing technique is usually used to improve spectral baselines. Each receiver generally has two sets of arbitrarily scaled numbers: a signal spectrum $S_{i}$, and a reference spectrum $R_{i}$. The basic difference between spectral line observing techniques is how $R_{i}$ is obtained. In the total power mode, the reference spectrum is obtained in a different region of the sky as a separate scan. If possible, the telescope should track the same path in the hour angle-declination plane. In the frequency switched mode, the reference spectrum is taken in a different part of the receiver bandpass. The computer driven L.0. is used to switch back and forth between signal and reference bands at a rate of 1 Hz , typically, during a single scan. In either case, the calibrated difference spectrum is obtained from

$$
\begin{equation*}
T_{i}=\frac{S_{i}-R_{i}}{R_{i}} T_{\text {sys }} \tag{6-4}
\end{equation*}
$$

Equation 6-4 provides a first order correction for the large scale instrumental profile. The assumptions which go into this calibration procedure are that the system temperature is uniform across the signal and reference passbands and that the signal to reference gain ratio in each channel is the same for all channels. Usually these assumptions are good to first order, but if a strong line is in the signal, or particularly the reference, or if widely separated parts of the frontend bandpass are used for frequency switching, or if the on source position contains a strong continuum source in total power, these assumptions may break down. A simple baseline subtraction will not necessarily compensate for differential gain across the passband.

In the total power mode, signal and reference spectra are obtained in separate scans, and the data passed to the on-1ine analysis computer are $S_{i}$ and $R_{i}$ in temperature units. The calculation in equation 6-4 must then be invoked by the observer in the on-line analysis computer. In the frequency switched mode of observing, however, the calculation of $T_{\text {i }}$ is performed in the on-line DDP116 computer, and the signal and reference spectra are not available for separate processing.

## 7. INTERFERENCE

Man-made and natural wideband interference such as ignition, power line and computer noise, oscillating TV boosters, relay arcing, and local thunder storms can be a severe problem when observing below 1 GHz . Although most of this noise has a very steep spectrum, it is sometimes strong enough to affect continuum observations at 21 cm . Since new man-made noise sources occur continually, an observer intending to make measurements below 1 GHz which would be affected by wideband noise should notify the Interference Office, Electronics Division, at least 2 weeks in advance so that steps can be taken to identify and alleviate the worst problems. Because the radiometers on the telescope are much higher above ground and more sensitive than those available in the mobile interference truck and at the lab, many of the problems will not show up until the receiver is installed on the telescope. If a problem is then encountered, the observer should seriously consider contributing some observing time, if necessary, to help find the source of interference. The Observatory personnel are on hand to help in any way possible, but they need as much information as the observer can provide.

Narrow-band interference is much more of a problem at lower frequencies, but errant radar signals or mixing products of lower frequency signals can occur at higher frequencies. Between 500 and 1000 MHz , band widths of 10 MHz or so can be used as long as one is careful to choose a clear frequency. Below 500 MHz band widths of 1 or occasionally 3 MHz are the maximum usable in most cases without encountering frequent bursts of aircraft transmissions. If one is confined to operating at a specific frequency, chances are high that a significant interfering signal will be within a few MHz of this frequency.

In general, interference originates in four categories of sources:

1. Internal to the radiometer in use, e.g., birdies, instabilities, etc.
2. Other radiometers and electronic equipment on the Green Bank site.
3. Government and nongovernment authorized transmitters within and outside the National Radio Quiet Zone (NRQZ).
4. Unintentional sources, natural and man-made.

### 7.1. INTERFERENCE INTERNAL TO THE RADIOMETER

Occasionally internal "birdies" or receiver instabilities appear to be external interference (or vice versa). Many types of interference are obviously external. Examples are: (1) Intermittent spectral spikes visible in the IF spectrum analyzer; (2) radar pulses or power line corona or ignition pulses or lightning crashes visible on the total power vs. time oscilloscope and/or audible on the audio monitor. If in doubt, ask the receiver engineer to check.

### 7.2. INTERFERENCE FROM ELECTRONIC EQUIPMENT ON GREEN BANK SITE

Most of our radiometers are potential sources of narrow-band interference. The most likely sources of interference are from highlevel signals leaking from telescope coaxial cables. Examples are the Universal Local Oscillator (ULO) in the 1 to 2 GHz range and several upconverter pumps. The interferometer transmits to and from the 45 foot on several frequencies near 1300 MHz and at 14.5 GHz . Also, harmonics of the 70 MHz clock in the interferometer digital delay are observed up to nearly 2 GHz .

Table 7-1 lists, by frequency, potential interference of electronic equipment. This list is updated periodically. If in doubt, check with the Interference Office. Spectral line observers should check this list before observing. Note that only a few of these signals will exist at any one time and most have never been seen as interference.

### 7.3. AUTHORIZED TRANSMITTERS

Transmitters are authorized in the U.S. throughout the radio frequency spectrum except for the very few primary-exclusive and prima-ry-passive radio astronomy bands. All U.S. Government transmitters are authorized by the FCC.

Only applications for new and modified fixed permanent transmitters within the NRQZ are reviewed by NRAO and kept at or below the criteria for allowable power density at Green Bank. A NRQZ Fact Sheet which lists the criteria is available from the Interference Office. The NRQZ procedures do not apply to temporary, mobile, airborne, balloon or satellite transmitters. Therefore, most interfering transmitters are beyond control by the NRQZ. Many interfering fixed transmitters on frequencies below 400 MHz are located outside the NRQZ. Some interfering transmitters inside the NRQZ are "grandfathered" in, such as those in the $73.0-74.6 \mathrm{MHz}$ exclusive radio astronomy band. Spectral line observations will detect signals far below the NRAO/NRQZ criteria for frequencies outside the radio astronomy bands.

The primary benefit of the NRQZ is that it controls the signal levels from fixed transmitters inside the zone to prevent radiometer overload at frequencies below 470 MHz , to minimize potential interference at frequencies above 470 MHz , to further minimize interference in the radio astronomy bands, and thus reduce the interference level from what it would be without the NRQZ.

The Interference Office, room 107 in the Jansky Lab, keeps TNIA lists of all known U.S. Government and non-government fixed transmitters located inside the NRQZ. The lists are updated once a year. The old Green Bank "Quik Look" 1ist is discontinued.

Since 1971, several interference surveys have been made. Those older than 2 or 3 years are obsolete. In 1981 surveys of rather low sensitivity were made in the $70-75 \mathrm{MHz}$ and $1000-2000 \mathrm{MHz}$ ranges. Contact the Interference Office for copies of those and more recent
surveys. Table 7-2 summarizes the major interference-loaded bands in the 70 to 2000 MHz range.

Table 7-3 1ists the WARC-79 Radio Astronomy Allocations for the U.S. up to 26 GHz . The WARC-79 allocations became effective in January 1982 but will not be implemented in the U.S. until later. Extra footnotes in Table 7-3 indicate the bands which have detectable signals. Table 7-3 is adapted from V. Pankonin, "Protecting Radio Windows for Astronomy", Sky and Telescope, April 1981.
7.4. UNINTENTIONAL SOURCES, NATURAL AND MAN-MADE

A troublesome type of interference is unintended radiation from various sources, especially at frequencies below 1 GHz . Obviously, NRAO has no control over natural sources such as lightning, sun, atmosphere and ionosphere. But we do have a degree of control over local man-made sources such as ignition, welding, power-line arcing, oscillating TV boosters, arcing switches and relays, computers, various on site electronic equipment, etc. For example, the interferometer links and digital delay system can be shut down by advance telescope scheduling.

The Green Bank staff person responsible for Local Interference Control tries to locate and eliminate potential interference from power lines and oscillating TV boosters, etc. An observer or telescope operator suspecting interference from local sources should immediately contact the Local Interference Control staff person via the Interference Office, Green Bank extension 107.

## 8. POINTING UNDER COMPUTER CONTROL

There are two computers involved in pointing the telescope, and both need certain input information if they are to work properly. This chapter is therefore divided into two major sections, each devoted to the input of a single computer.

At the more basic level is the H 316 computer which performs the coordinate transformations. It needs to know the right ascension and declination pointing correction curves, the nominal level curve, the focal length of the telescope, and beam deflection factors for the Sterling mount and travelling feed (see Chapter 4). Cards containing nominal values for all of these items are already present at the telescope, except for those receiver/feed combinations that have never been pointed. Optional pointing corrections can be read into the H316 if the observer has made some pointing checks (see Chapter 4 for recommended procedures). The card formats for H316 instructions are described in section 8.1 .

The DDP116 computer operates more at a supervisory level, and the particular concern of section 8.2 is that of scheduling an observing program to take data while the telescope is on source; that is, preparing a deck of source cards. Without this there is no observing program. There are two basic ways to point the telescope during an observation: (1) to track a source, or (2) to scan across the source. Tracking is more closely associated with line observing while scanning is more closely associated with continuum observing, but this association is not absolute. Both pointing modes are available in a number of different coordinate frames. The various pointing modes that are available, and their associated source card formats are discussed in section 8.2, along with comments on scheduling, and computer programs available to assist in scheduling.

### 8.1. ENTERING POINTING CORRECTIONS

Chapter 4 consisted of a discussion of the origin of pointing errors and the methods of correcting these errors. Basically, position encoders mounted on the telescope are part of a feedback loop for keeping the telescope on position. The position encoder readings give the indicated coordinates of the telescope position. These are close to the true or apparent coordinates on the sky, but differ due to encoder offsets, axis misalignments, and deformations of the telescope structure due to gravity and differential heating by the sun. The apparent coordinates of a celestial source can be found in a straightforward way, but the pointing errors must be known to determine what indicated coordinates should be commanded. The difference between apparent and indicated coordinates is the pointing correction. Since the pointing corrections are small, right ascension and declination pointing corrections are treated separately. The pointing corrections are implemented as functional forms with coefficients that can be varied. The H316 computer, which performs the coordinate transformations, must read the coordinates of these functional forms from cards. This section
describes the content and format of those cards. A sample H316 input card deck is shown in Figure 8-1.

A typical H316 input card sequence consists of right ascension pointing curve coefficients (read from an " $A$ " card), declination pointing curve coefficients (" $D$ " card or cards), nominal level curve coefficients ("L" card), and focal length, beam deflection factors, critical angles, and additional beam deflection factors for the travelling feed and Sterling mount (" T " card). There are different sets of declination pointing curve coefficients for different receiver/feed combinations, so there can be a number of " $D$ " cards, each carrying a two character identifying code. Instructions given to the DDP116 computer (on " S " cards, see Chapters 9 and 10), tell which set of declination coefficients the H316 is to use.

Chapter 4 also described pointing corrections called PVALS, and how to determine them. They are used to correct for small feed offsets, which may change when a receiver is re-installed. They may be read into the H316 on a "P" card. IF PVALS ARE NOT USED MAKE SURE THAT A "P" CARD WITH ZEROES IS IN THE H316 INPUT CARD DECK.

### 8.1.1. RIGHT ASCENSION POINTING CURVE COEFFICIENTS: "A" CARD

The right ascension pointing correction equation is

$$
\begin{equation*}
\Delta \alpha=m+n \tan (\delta)+c \sec (\delta) \tag{8-1}
\end{equation*}
$$

where $\delta$ is the indicated declination, and where $\Delta \alpha, m, n$, and $c$ are in seconds of time. This is the offset equation for a transit circle whose axis is displaced from true east-west and from the horizontal. The current values of $\mathrm{m}, \mathrm{n}$, and c are listed in Table $8-1$, and are entered into the H 316 computer on an " A " card. The " A " card format is given in Table 8-2. A nominal right ascension pointing correction curve is plotted in Figure 8-2.

### 8.1.2. DECLINATION POINTING CURVE COEFFICIENTS: "D" CARD

The declination pointing correction equation is more complex than the right ascension pointing correction because the dish deformations are not easily modeled. The equation is

$$
\begin{equation*}
\Delta \delta=C_{0}+C_{1} \delta+C_{2} \delta^{2}+C_{3} \delta^{3}-\Delta L \tag{8-2}
\end{equation*}
$$

where $\Delta \delta$ is in arc seconds, $C_{0}, C_{1}, C_{2}$, and $C_{3}$ are the pointing coefficients for a particular combination of receiver and feed, and $\Delta L$ is the level curve correction, described below. Particular sets of declination pointing coefficients are identified by a two character identifier. The most recently determined coefficients are given in Table 8-1. Ask the "Friend" about more recent updates to the pointing coefficients. The declination pointing coefficients are entered via a "D" card. The "D" card format is given in Table 8-3, along with a list of the identifiers recognized by the program. Identifiers listed in Table 8-3 but not in

Table 8-1 correspond to receivers that have not been pointed. Typical declination pointing correction curves are plotted in Figure 8-3.

### 8.1.3. LEVEL CURVE COEFFICIENTS: "L" CARD

An electronic level mounted on one of the telescope support towers measures the structural tilt in the north-south direction. Part of the tilt as a function of declination is due to the fact that the telescope is not perfectly balanced, and so there is an unavoidable bending of the structure. The level curve is this nominal relationship between the electronic level reading and the indicated declination. The declination pointing correction equation takes this effect into account. However, the telescope also tilts due to the uneven heating by sunlight and due to wind, and these effects are not accounted for in the nominal declination corrections. This extra tilt is the measured level reading minus the nominal level curve:

$$
\begin{equation*}
\Delta L=\bar{L}-\left(L_{0}+L_{1} \delta+L_{2} \delta^{2}+L_{3} \delta^{3}\right) \tag{8-3}
\end{equation*}
$$

where $\Delta \mathrm{L}$ is in arcseconds, $\delta$ is the indicated declination, $\bar{L}$ is the ten second average level reading, and $L_{0}, L_{1}, L_{2}$, and $L_{3}$ are the nominal level curve coefficients. The current vafues of the level curve coefficients are listed in Table 8-1, and are entered into the H316 via an "L" card. The "L" card format is given in Table 8-4. A positive level correction is in the sense of a northward tilt, and so the level correction is subtracted from the declination correction. A typical level curve is plotted in Figure 8-4. Experience has shown that the shape of this curve is quite stable but that the zero point changes with time. It is not known whether these changes consist of a continuous drift or discrete jumps.

### 8.1.4. BEAM DEFLECTION DATA: "T" CARD

Besides the information on the " $A$ " card, an additional right ascension pointing correction is necessary for observing off axis. The beam deflection factor (BDF) is the ratio of the angular displacement of the beam to the angular displacement of the feed in the east-west direction. At large feed displacements, obtainable only on the travelling feed, the BDF changes abruptly. The critical angle is the angular distance of the feed where the BDF changes. A third parameter tells the copputer the change in slope at this critical distance as a fraction of $2^{15}:$

$$
\begin{equation*}
\Delta B D F=\frac{\Delta T}{T} \times 2^{15} \tag{8-4}
\end{equation*}
$$

where $\Delta T$ is the pointing error in seconds of time incurred by using the central $B D F$ and $T$ is the time in seconds from the critical angle to the time of observation. The computer uses the focal length of the telescope, 1525.0 inches, to compute the angular displacement of the feed. All of these data are entered on $a$ " $T$ " card, short for travelling feed. The format for the " $T$ " card is given in Table 8-5. Nominal values are given in Table 8-1.

### 8.1.5. PVALS: "P" CARD

Corrections for small feed offsets may be entered as PVALS, i.e.,

$$
\begin{align*}
& \Delta \alpha=\left(m+P_{2} / 4\right)+n \tan (\delta)+\left(c+P_{1} / 4\right) \sec (\delta) \\
& \Delta \delta=\left(C_{0}+60 P_{3}\right)+C_{1} \delta+C_{2} \delta^{2}+C_{3} \delta^{3}-\Delta L \tag{8-5}
\end{align*}
$$

The procedure for determining the PVALS was given in Chapter 4. The PVALS are entered on a " $P$ " card, the format of which is given in Table 8-6.

### 8.1.6. TRAVELLING FEED RECEIVER OFFSETS: "B" CARD

Although the box offset card, or " $B$ " card, is input into DDP116 rather than the H 316 , it is worth mentioning at this time because of its effect on pointing and its effect on scheduling. The travelling feed box ( $0.3-1 \mathrm{GHz}$ ) allows two feeds to be installed for observations at $300-500 \mathrm{MHz}$ or $500-700 \mathrm{MHz}$, and $700-1000 \mathrm{MHz}$. The two feeds are physically offset from center by $\pm 34$ inches, so that the whole box must be moved to get either feed on axis. The $300-700 \mathrm{MHz}$ receiver is located East on the box ( -34 inches), and the $700-1000 \mathrm{MHz}$ receiver is located West on the box (+34 inches). These offsets are entered on a " $B$ " card in the observer's setup deck for the DDP116 computer, which passes the value to the H316. The "B" card format is given in Tables 9-3 and 10-5.

The effect of the box offsets on the hour angle limits of this receiver is discussed in Appendix D. The point to remember is that for a tracking scan the source peaks up at the box offset. For example, the two low frequency feeds peak up at -34 inches of travel. This means that a source can be tracked for less time before transit and more time after transit. The 98 inches of travel before transit correspond to $12^{\mathrm{m}} 20^{\mathrm{s}} \mathrm{sec} \delta$ of right ascension, and the 166 inches of travel after transit correspond to $20^{\mathrm{m}} 55^{\mathrm{s}} \mathrm{sec} \delta$. The calculations for the high frequency side of this receiver give the reverse answers. It is advisable to calculate these maximum offsets in beamwidths, heeding the advice of section 3.3 .1 that there is little to be gained by tracking more than 5 HPBW's off axis, due to the loss of aperture efficiency.

### 8.2. SEQUENCING AN OBSERVING PROGRAM: SOURCE CARDS

The DDP116 computer performs the task of implementing an observing program. To do this it reads instructions from cards, and acts on them sequentially. Each source card contains pointing instructions and equally important timing instructions. The computer will record data between the specified start and stop times. There is a variety of source card formats, as shown in Figure 8-5. The format for interpreting source cards is coded onto the card as the position code or pointing mode. Part of the variety in pointing modes is due to the number of different coordinate frames in which pointing and timing instructions can be specified, and part is due to variations on the themes of tracking a position on the sky and scanning across the sky. The different coordinate frames were discussed in Chapter 4, and are reviewed here before going on to sections which discuss in general terms the limitations on tracking and scanning imposed by the telescope hardware itself. The restrictions on tracking are only a subset of those on scanning, and so an observer planning to observe in a scanning mode should first read the section on tracking. A third section describes the available pointing modes, and a fourth section describes computer programs available to assist in preparing decks of source cards.

The telescope position may be commanded in a number of coordinate frames of reference. The H316 computer performs the computations necessary to convert from one frame to another. The four frames that are used are epoch, apparent or true, indicated, and galactic. The epoch coordinate frame consists of positions in equatorial coordinates at a given epoch. The only epoch now available is 1950.0. The apparent coordinate frame consists of positions in equatorial coordinates at the epoch of the observations. The difference between epoch and apparent coordinates is precession, aberration, and nutation from 1950.0 to the epoch of the observations. The indicated coordinate frame consists of positions as indicated by the position encoders on the telescope. Quite literally, the indicated coordinates are "what the dials read." The differences between apparent and indicated coordinates are due to slight misalignments in the telescope axes, encoder offset errors, and deformations of the telescope structure due to gravity and differential heating by the sun. The galactic coordinate frame consists of positions in new galactic coordinates. These coordinates are transformed to 1950.0 equatorial coordinates, and then treated as epoch coordinates. That is, they are precessed to the present epoch and pointing corrections are added.

### 8.2.1. TRACKING MODES

The most fundamental limitation on tracking, of course, is that the 300 foot was designed as a transit instrument. Tracking in right ascension is accomplished by moving the feed in the focal plane. There are two feed carriage systems. One is a 14 m , fixed focus east-west set of rails, called the travelling feed, used for frontends below 1 GHz . The other, called the Sterling mount, is a more accurate mount for radiometers above 1 GHz and is capable of focusing, rotation and eastwest translation up to 45 cm on either side of the telescope axis.

Hour angle limits are $\pm 15$ inches or about $\pm 2^{m}$ sec $\delta$ around the telescope's meridian on the Sterling mount (used above 1 GHz ) and are $\pm 275$ inches or about $\pm 28^{m} \sec \delta$ on the travelling feed carriage. Hour angle limits using the $300-1000 \mathrm{MHz}$ carriage on the travelling feed are $\pm 132$ inches (reference: Appendix D), allowing a total tracking time of about $33^{\mathrm{m}} \mathrm{sec} \delta$, but the feeds are offset from the center of the box making the tracking limits asymmetrical (see section 4.2.3). The limits in terms of time are very slightly dependent on frequency and aperture illumination as explained in the section on beam deflection factor. Here again it should be remembered that precession and pointing corrections will make these limits asymmetric about the true or 1950 meridian.

The primary indicated declination limits are nominally $+89^{\circ} 50^{\prime}$ and $-18^{\circ} 30^{\prime}$ but may vary by a few arcminutes depending on temperature. Indicated coordinates are those indicated by the position encoders on the telescope structure, but they are quite close to the actual position on the sky. Beyond these limits the telescope can be driven manually to back-up limits of $+91^{\circ} 04^{\prime}$ and $-19^{\circ} 30^{\prime}$ with the variable speed motor. When operating in card control mode, it should be remembered that these limits are indicated and a 1950 or true position may be beyond the limits after precession and/or pointing corrections are applied. If a primary limit will be encountered, the telescope will not move under computer control from the current position.

Another important limitation on the scheduling of an observing program is the time it takes to move from one source to the next. When a series of cards is read into the computer, the first card is acted upon immediately and the second takes control at the stop time of the first and so forth. Sufficient time must be allowed for movement of the telescope in declination at $10^{\circ} /$ minute plus about 5 seconds for position $\operatorname{trim}_{2}$ and in hour angle at the rate of 30 inches per minute ( $240^{\mathrm{s}} \mathrm{H} . \mathrm{A} . / \mathrm{min}$ at the equator) on the Sterling mount and 90 inches per minute ( $720^{\mathrm{S}} \mathrm{H} . \mathrm{A} . / \mathrm{min}$ at declination $=0^{\circ}$ ) on the travelling feed [32], plus 4 or 5 seconds for trim. The trim time may be reduced if a position error of a few arc minutes can be tolerated at the start of a scan. Two motors are used for declination drive. One provides continuously variable speeds from 0 to $2: 25 /$ minute ( 0 to 1351 minute), and the slew motor has a fixed nominal speed of $10^{\circ} /$ minute. A three second time delay is built into the declination drive system to allow for telescope deceleration before reversal of direction of travel or speed change. A rule of thumb for slewing to a new position is to add five seconds to the time required to slew at $10^{\circ} / \mathrm{min}$ for deceleration and position trim. Additional time may also be required for receiver adjustments.

There are two pointing modes available for tracking. Both require source positions in epoch 1950.0. The difference between them is that in one mode (mode 8), start and stop times are specified as local sidereal times (LST) at the epoch of the observations. In the other mode (mode 18), start and stop times are specified as 1950.0 LST times. This choice of start and stop time frames of reference is available for declination scans as well.

The advantage of scheduling start and stop times in 1950.0 LST times is that it is very simple to set up the maximum length observation. The declination gives the maximum length of time that a particular source can be tracked. Subtracting half of this time from the 1950.0 right ascension gives the earliest possible start time, and adding half of the scan length to the right ascension gives the latest possible stop time. There may be other restrictions on the scan length, for example those imposed by the autocorrelator, but it is still easier to schedule a single scan in mode 18 , with 1950.0 start and stop times.

The advantage of scheduling start and stop times in current LST times becomes apparent in a schedule with many sources closely spaced in right ascension. The scheduling of such as observing program will very much depend on the time it takes to get from one source to the next. These computations are easy if start and stop times are in current LST times, but not if they are in 1950.0 LST times because of the need to precess and nutate the commanded positions to recover current start and stop times.

There are some computer programs available for preparing an observing program which make the choice of timing mode less momentous. A program called LINE300 prepares source cards with current LST start and stop times, for ease of scheduling, but also with start and stop times computed to allow for the maximum scan length. Another program, PLAN300, scans a deck of source cards, computing the time required to move to the next source, skipping down through the deck until it finds the next source that it can get to in time. These programs are described in a separate section in this chapter.

### 8.2.2. SCANNING MODES

All of the available pointing modes make provisions for scanning across the sky. Right ascension scanning rates may be specified for the two tracking modes described in the previous section. In the other modes, right ascension scanning is at the sidereal rate as the sky drifts by with the telescope at zero hour angle. Declination scanning rates can be specified in most of the other pointing modes.

The simplest scanning mode is the drift scan, where the telescope remains motionless while the source drifts through the beam (or beams). Ground pick-up in the sidelobes is unchanged during a drift scan, which results in good baselines for continuum observing, necessary for accurate flux determinations. The declination for a drift scan may be commanded in epoch (mode 3), apparent (mode 2), or indicated (mode 1) coordinate frames, with start and stop times specified as current LST. If an epoch declination is specified, start and stop times may also be specified as 1950.0 LST times. As was the case with the tracking modes, there is a program, PREP300, which calculates current LST start and stop times centered on the right ascension of the source, where the right ascension is given in the 1950.0 coordinate frame.

Scanning rates may be specified in most of the observing modes. The DDP116 computer sequences operations so that the computer is at the
position specified on the card, moving at the specified rate, at the specified start time. The position at later times can then be determined from the initial position, time from the start of the scan, and scanning rate. This is not true if the telescope is still moving to get on source when data taking begins. In continuum observations it is possible to avoid this problem by setting a flag to delay data taking until the telescope is within 20 arcseconds of being on source by placing a " 1 " in column 56 on the source cards.

Source cards are acted upon sequentially, as they are read. If the time between scans is long, the computer may try to back the telescope into a limit so that the specified scanning rate will put the telescope on source at the specified start time. To avoid this problem, there is a dummy pointing mode (mode 0). When a dummy card is encountered, the telescope moves to the commanded declination and waits. The time specified in the start time field is actually a release time: at that time the computer looks at the next source card and acts upon it.

A right ascension scanning rate may be specified on cards in the two tracking modes. This allows scanning at rates other than the sidereal rate. This mode of observing is limited by the hour angle coverage of the receiver mount in use and by the drive rates of the motors. Maximum hour angle drive rates on the movable feed systems are 0.5 inches $/ \mathrm{sec}$ (about $1 \% / \mathrm{min}$ ) on the Sterling mount and 1.5 inches $/ \mathrm{sec}$ (about $3^{\circ} / \mathrm{min}$ ) on the travelling feed carriage. Note that hour angle and right ascension rates are not the same due to the apparent motion of the sky.

A declination scanning rate can be specified in most observing modes. Observations to determine declination pointing are usually made while simultaneously tracking in right ascension (modes 8 and 18). Declination scans without hour angle motion can be made in pointing modes $1,2,3$, and 13. A dummy card may be necessary to avoid commanding a position outside the telescope limits if there is a long time between scans. Any declination rate up to 130 '/min may be specified in steps of $1^{\prime} / \mathrm{min}$. A fast slew rate of $600^{\prime} / \mathrm{min}$ can be used, but the motion is less predictable because the single speed slew motor is used with no provision for vernier rate trim. If this high rate is to be used, it is best to specify a rate of about $620^{\prime} / \mathrm{min}$ to prevent the computed position from getting ahead of the actual position and momentarily shutting down the slew motor. One other consequence of not having rate trim at high speed is that the acceleration time of the telescope causes a lag of about $50^{\prime}$ behind the 600 'min computed position which cannot be made up.

Wobbles (mode 6) provide a capability for alternately scanning north and south at a specified rate between two specified declination limits. One use for wobbles is to measure efficiency vs. hour angle by scanning across a continuum source a number of times, giving both the source deflection and baseline. There is a delay of 6 seconds between passing out of the declination range and re-entering it travelling in the opposite direction to allow time for reversal. Data is taken continuously, even during reversal, however.

Dummy card (0). The dummy card is used to hold the telescope at a particular declination in anticipation of further commands. Parameter l (Figure 8-5) is read as an indicated declination, and the time in the start time block is interpreted as a release time to execute the commands of the next card. The dummy card is useful for setting up near the start position of a variable declination scan, thus preventing the telescope from encountering a declination limit by picking up a computed track long before the start of data taking. It may also be used to set the telescope for a drift scan through a calibration source to be recorded on a chart record. No data is put on tape with this card, and the feed is automatically driven to center track.

Indicated declination card (1). This card drives the telescope to the indicated declination specified by parameter 1 , and data is put on tape between the current LST start and stop times. A declination rate entered as parameter 3 in arcminutes per minute may be used to drive the telescope at a constant rate with the feed at center track. This motion is closed-loop, meaning that the commanded declination is computed at frequent intervals so that the position of the telescope at any given time is completely predictable. Any declination rate up to $130^{\prime} / \mathrm{min}$ may be specified in steps of $l^{\prime} / \mathrm{min}$. A fast slew rate of $600^{\prime} / \mathrm{min}$ can be used, but the motion is less predictable because the single speed slew motor is used with no provision for vernier rate trim. If this high rate is to be used, it is best to specify a rate of about $620^{\prime} / \mathrm{min}$ to prevent the computed position from getting ahead of the actual position and momentarily shutting down the slew motor. One other consequence of not having rate trim at high speed is that the acceleration time of the telescope causes a lag of about $50^{\prime}$ behind the $600^{\prime} / \mathrm{min}$ computed position which cannot be made up.

A feed rotation angle may also be specified on the indicated declination card as parameter 4. This angle is measured eastward from north on the sky. Slew rate for rotation angle on the Sterling mount is 13.3 degrees/second and limits are $\pm 200^{\circ}$. No rotation is provided on the travelling feed mount. The position and polarization angle of the beam(s) at zero rotation angle may be found in the electronics division reports on the individual feeds, or front end boxes, or on receiver installation sheets.

True declination (2). This card has exactly the same function and controls as the indicated declination card except that parameter \#1 is interpreted as true declination. The difference between true and indicated position is the declination pointing correction.

1950 declination (3). This card is identical to the indicated declination card except that parameter 1 is interpreted as 1950.0 declination. The difference between indicated and 1950.0 declination at the 300 foot is the declination pointing correction plus precession, aberration and nutation.

Constant galactic latitude (4). Position code 4 provides for scanning at a constant galactic latitude (new galactic coordinates) by moving the declination of the telescope at a slowly varying rate with the feed box at center track. The feed box is continuously rotated
during the observation so as to maintain a constant galactic rotation angle. The latitude is specified by parameter 1 in decimal degrees and the angle by parameter 4. Galactic rotation angle is defined for this purpose as the angle measured counterclockwise on the sky from the direction of the north galactic pole. By pointing the center of a receiver box at a constant latitude and maintaining a constant galactic rotation angle, each beam of a multibeam frontend system follows a constant latitude. The chosen value of rotation angle should allow for variation during the observation without impinging on the rotation limits of $\pm 200^{\circ}$ with respect to the direction of the north celestial pole. Note that in pointing modes 4 and 5 there are problem areas in the sky where lines of constant latitude or longitude, respectively, are almost parallel to lines of constant right ascension.

Constant galactic longitude (5). With this card a constant galactic longitude (new galactic coordinates) is maintained by continuously varying the telescope declination with the feed at center track. No provision is made for automatically maintaining a constant galactic rotation angle. The coordinate $1^{11}$ is entered as parameter 1 in decimal degrees.

Wobbles (6). The wobble card initiates a zig-zag track in the sky by driving the telescope at a rate specified by parameter 3 alternately north and south with the feed at center track. The motion is closed loop, and all of the rates and limitations outlined in this and the previous section apply here. The sign on the declination rate is ignored, and the first track is always northward. A dummy card (0) is useful in setting up just south of the south limit to allow a smooth start.

Parameters 1 and 2 are the south and north indicated declination limits, respectively, between which the wobbles are performed. There is a delay of 6 seconds between passing out of the declination range and reentering it travelling in the opposite direction to allow time for reversal. Data is taken continuously, even during reversal, however. No provision is made for card control of rotation angle.

Celestial coordinates (8). This is one of two card types which allow computer control of hour angle. Within the hour angle limits of the travelling feed or Sterling mount, a position in the sky can be tracked or scanned in right ascension and/or declination. Positions in parameters 1 and 2 are in 1950.0 coordinates, which means that the on-line computer will apply pointing corrections, precession, aberration and nutation.

Parameter 4 specifies a declination rate, and all of the limitations outlined in the indicated declination card section apply here. The right ascension rate is entered as parameter 3 in arcminutes per minute on the equator in $1 / / \mathrm{min}$ increments. The maximum east-west tracking rate of either the travelling feed or Sterling mount is 0.25 inches/s or about +3 and -1 minute of time per minute in right ascension depending on the BDF. For the travelling feed, the travel limits are $\pm 275$ inches (about $9^{\circ}$ ), the maximum slew rate is 2.0 inches/s, and the maximum position error in the east-west direction is
$\pm 0.5$ inches or about $\pm 1$ arcminute. For the Sterling mount, the travel limits are $\pm 15$ inches (about $0: 5$ ), the maximum slew rate is 0.5 inch$\mathrm{es} / \mathrm{s}$, and the maximum system position error is $\pm 0.086$ inches or $\pm 10$ arcseconds.

In specifying start and stop times on the position code 8 card, one must keep in mind that these times must be centered on the indicated source position if the source is to be tracked for an equal time on either side to the feed track center, while the source position itself is in 1950.0 coordinates.

1950 Declination (13). This card is identical to the 1950 declination (3) card except that start and stop times are referenced to 1950 coordinates. These times are converted to LST by adding precession, aberration, nutation, and pointing corrections. Caution must be used to avoid start and stop time conflicts when source scheduling due to the fact that precession and pointing corrections are different at different declinations.

Celestial coordinates (18). This card is identical to position code (8) except that start and stop times are referenced to 1950 coordinates. These times are converted to LST's by adding precession, aberration, nutation, and pointing corrections. This card is more convenient for producing scans symmetric about the telescope meridian from 1950 coordinates, but because precession is different at different declinations, one must be careful to avoid stop and start time conflicts when scheduling sources in close succession.

### 8.2.4. COMPUTER PROGRAMS FOR PRODUCING SOURCE CARDS

There are a number of computer programs available which facilitate the production of source card decks. There is also a program which reads in observing decks and simulates the observing sequence to help optimize the timing of the observations. This program is useful for any observing deck, not just those produced with the aid of the computer programs that are described here. If many sources are observed in an identical manner, or nearly so, these programs may help reduce the drudgery of punching up observing decks. The programs run on the Charlottesville IBM computer and can do the actual card punching on a remote punch in Green Bank. The programs can do the transformations from 1950.0 coordinates to the present so that start and stop times can be specified in current LST for ease of scheduling. One need supply only the 1950.0 coordinates of the sources to be observed and parameters of the observing procedure such as positioning mode, scan length, integration time, etc., and the programs will precess the positions, add in pointing corrections, compute start and stop times, and punch the cards. There is a feature whereby well-known calibration sources (such as VLA calibrators) can be specified by name only, and the program will look up the positions. The purpose of this section is simply to make the observer aware of these programs. Here we describe in general terms what these programs do and where to find them. Complete instructions for running these programs are found within the program listings, which are given in Appendix $C$.

The programs described here were originally written to assist the staff with the kinds of observations necessary to maintain telescope performance, such as pointing and gain calibration, and therefore they are not completely general in their application. For example, pointing in galactic coordinates (pointing modes 4 and 5) is not currently supported by a card producing program. The programs reside on the Pandora data set with logon GBOPER (for Green Bank Operations). If you are unfamiliar with the Pandora system on the Charlottesville computers, the "friend" or a computer programmer can help you get started. The details of running the programs can be found in a descriptive comment at the beginning of each program listing. The program comments can be found in Appendix $C$ to this manual, or in Pandora members with names corresponding to the program names. Most of the JCL has been hidden away in catalogued procedures, simplifying the job of running these programs. Listings of the calibrator files can also be found in this manual, in Appendix B. These files contain the sources that the programs recognize by name, and are excellent sources of suitable calibrators.

There are three programs which produce punched cards. Programs POINT300 and PREP300 punch cards for continuum declination scans and drift scans or wobbles, respectively. Program POINT300 prepares cards for positioning codes $3,8,13$, and 18 , observing with a pulsed cal. The scan length and scanning rate may be specified provided that they do not violate constraints imposed by the Sterling mount. The program needs to be supplied with the coefficients of the right ascension pointing correction curve, which can be found in Table 8-1 of this manual. Program POINT300 is primarily intended for preparing observations to check the declination pointing of the telescope. Program PREP300 prepares cards for positioning codes 13 and 18. Cards for wobbles may also be produced, but they are somewhat different from positioning code 6, including provisions for offset feeds and multiple feeds. Drift scans of any length can be set up. High declination drift scans are automatically lengthened. Declination scanning rates can be applied. A series of declination offsets can be applied to cards for use on successive days for mapping or for measuring beam shapes. This program also requires certain input numbers found in Table 8-1 of this manual. A version of PREP300 with a slightly different input format, in use before July 1982, is still available under the name OLDPREP.

The third card producing program is LINE300. Program LINE300 is for preparing observing cards for spectral line observations in pointing modes 8 and 18. The program is essentially the same as POINT300 in these two pointing modes except that the timing of scan lengths and intervals between scans is adjusted to conform with peculiarities of the autocorrelator, and that a serfes of scans is produced for each source, with off source scans symmetrically arranged about an on source scan for total power observing. The number of off source scans on each side of the on source scan can be specified, and can be set to zero for switched power observing. The default value for the scan length is the maximum amount of time that the Sterling mount can track, rounded down to a multiple of 20 seconds. The program could be used to prepare source cards for any observing program that involved tracking.

The scheduling program is PLAN300. The straightforward way of using it is to take cards produced by the programs just described, or by hand at the keypunch, add a few cards that invoke program PLAN300 and submit the deck via the remote card reader next to the line printer in the Jansky lab (rm. 234). The required card images can be found in the program listing in the GBOPER Pandora member named PLAN300. The source cards should be arranged in order of start time. The current version of PLAN300 assumes that start and stop times on source cards are current LST time, i.e. this program cannot do precession. The program goes through the input source cards calculating the time necessary to move and set up for the next source. If that time comes after the specified start time, then that source is set aside temporarily. All of the sources that are kept make up the observing schedule for the first day. Then the process is repeated with all of the sources that were skipped, yielding schedules for successive days until all of the input sources are scheduled.

There are other, more highly specialized programs that run offline. These include programs for measuring the level curve, pointing curves, and gain curves. Observers who intend to make extensive pointing and calibration observations should ask the "Friend" about these programs.

## 9. SPECTRAL LINE OBSERVING

The purpose of this chapter is to describe the on-line computer programs for spectral line observing that run on the DDP116 computer, and the setup cards necessary for each. These setup cards contain information that the computer uses to check the configuration of the autocorrelator, to command the L.O. system, and to point the telescope, among other things. Setup cards followed by source cards constitute an observing deck. Source cards were discussed in Chapter 8, except for certain options pertaining particularly to spectral line observing.

The basic component of the spectral 1 ine system is the Model III autocorrelator, discussed in detail in Chapter 6. The autocorrelator is the digital equivalent of a filter bank with detectors and analog-to-digital converters. The autocorrelator also sends signals which control various schemes to stabilize against gain fluctuations and to allow automatic determination of the system temperature.

The autocorrelator contains 384 spectrometer channels, but this total can be broken up to accommodate from one to four receivers. The breakdown is into quadrants of 96 channels each. In the three receiver mode, the channels are allocated to spectra of 96,96 , and 192 channels. The on-line computer reads setup parameters for the autocorrelator from cards.

Stability against gain fluctuations is achieved by comparing two spectra which are presumed to be affected equally by any gain drifts. The two spectra will be referred to as the signal and reference spectra. The two modes of observing that are currently supported are referred to as "switched power" and "total power", and the difference between them is the way the reference spectrum is obtained. In the switched power mode, the observing time is equally (usually) divided between the signal band and a reference band of frequencies, with the reference band centered on a different frequency ("frequency switching"). In the total power mode, the signal and reference spectra are summed in separate scans taken at different positions on the sky, flagged as "on" source or "off" source, with no frequency switching.

There are three on-line spectral line programs. SPOWR3 and MPOWR3 are switched power programs. The major difference between them is how often data accumulated in the DDP116 computer are written to tape. SPOWR3 is normally used where long integrations are taken at a single point in the sky. The integration time is set at the control console and is usually a compromise between keeping the off-1ine data averaging to a manageable amount and having the ability to eliminate interference in one or more records (integration periods) without losing too much data. The integration time must be set to an even multiple of the correlator dump time, which is typically 10 seconds. MPOWR3 is normally used for spectral line mapping, and spectra are recorded on tape every correlator dump cycle. Both signal and reference spectra are recorded on tape in both of these programs, although only the final switched difference spectrum is available in the on-line analysis computer. TPOWR3 is the total power program. Jt records a single spectrum on tape at the chosen integration period, which must be an even multiple of the
correlator dump time. A code on the source cards can be used to indicate whether a scan is a signal or "on source" spectrum or whether it is a reference or "off source" spectrum. For reasons associated with the on-line analysis program POPS, this feature simplifies the processing of total power data, provided that the "off" is obtained before the "on" spectrum.

A11 three programs require the same types of setup cards, and so sections of this chapter describe the types of input cards rather than the three programs. A sample setup card deck for spectral line observing is shown in Figure 9-1. The " $S$ " card contains information pertaining to a single receiver channel, such as noise tube value and information required to set the L.0. frequencies correctly. There must always be four " $S$ " cards, as if four receivers were in use. Besides the " S " cards, pointing cards, and source cards, the input deck may contain "L" cards, which set and check the automatic L.O. system output as desired, and an " $E$ " card, which changes the equation relating L. O. frequencies and sky frequency to accommodate receivers with up-converters.

The spectral line system has some limitations which should be kept in mind when making up source cards:

## NOTE:

Because of computer-autocorrelator timing requirements, the difference between start and stop times on the observing cards should be at least $1^{s}$ more than an integral multiple of integration periods, otherwise the last integration may not get on tape. Successive start times should not differ by multiples of $10^{\mathrm{S}}$ (e.g., $223956,2246 \mathrm{l}$ ) . This can occasionally cause autoorrelator sequence errors. Also, the time between the end of one scan and the beginning of the next scan must be at least $11^{\mathrm{s}}$.
9.1. SETUP CARDS: "S" CARD

Each setup "S" card contains information for a particular receiver. The information required on each "S" card, and the card format are shown in Table 9-1. Four " $S$ " cards are required (one each with $A, B, \underline{C}$, and $D$ in column 31) no matter which receiver configuration is used. The comment in columns $11-30$ must agree exactly on all setup cards. The pointing coefficient identifier (columns 6 and 7) is transmitted to the H316 computer in order to select the proper declination pointing curve for the observations, as described in section 8.1.2. Table 8-3 1ists the available identifiers. The pointing code (columns 34 and 35) specifies which of the feed offsets on the " $F$ " card (described below) applies to the channel specified by the " $S$ " card.

The inversion indicator (column 37) controls whether the velocity or sky frequency increases with increasing channel number, both on the on-line display scope and as the data are written on tape. To make the velocity increase from left to right on the display scope, the inversion indicator should be 0 if the first local oscillator is lower than the
sky frequency (upper sideband) and 1 if it is higher than the sky frequency (lower sideband).

The noise tube temperature (columns 38-43) is used to assign a vertical scale and system temperature to the off-line spectrum. Normal$1 y$, nominal values from the receiver installation data sheets are entered here in Kelvins, with corrections for aperture efficiency and so forth to be done in a later stage of data reduction. The decimal point must be in column 41.

The spectral line rest frequency, $f_{o}$, (columns 47-55) is used both on and off line in the radial velocity calculations and is expressed in Hz with no decimal. The center frequency formula (columns 56-73) is a FORTRAN expression for off-line computing of the center sky frequency from the IF and local oscillator frequencies. The symbol convention is as follows: L1 is the ULO primary frequency, $\mathrm{F}_{0} ; \mathrm{L} 2$ is the corresponding frequency if a second LO is used; and LA, LB, LC, and LD are the IF's dialed into the IF processor in channels $A, B, C$ and $D$, respectively. Typical equations would be $4 * \mathrm{Ll}+150.0$ or $4 * \mathrm{Ll}+\mathrm{LA}$. If the L.O. is under computer control, the sign before the IF frequency should be a plus. To indicate that the lower sideband of the L.O. frequency is to be observed, a negative IF frequency should be specified on the "L" card (described below). If the L.O. is in manual control, which means that there cannot be an "L" card, then the sign in front of the IF in the sky frequency equation can be used to select the proper sideband. In the manual mode, the IF frequency assumed by the computer is the output of the counter in the IF processor, which is always positive. Proper sideband selection can also be affected by the "E" card used with up-converter receivers.

The multipliers M and N (columns 74-77) from the first " S " card are used in the automatic computation of L.O. frequencies, as explained below. M is the factor by which the synthesizer frequency is multiplied before the L.O. signal is sent up to the frontend box, and $N$ is the multiplication factor in the front end. The ULO has a built in multiplier, so for almost all setups using the ULO, $M$ is 4 . The value of $N$ depends on the front end box in use, and both $M$ and $N$ can be obtained from the receiver installation information sheet, or from the receiver engineer.

The velocity reference indicator (column 78) specifies the rest frame in which radial velocities are computed off-line. The same rest frame is used in interpreting velocities in the automatic L.O. computations. Zero ( 0 ) causes no radial velocity corrections to be made, 1 refers radial velocities to the local standard of rest (LSR), 2 refers them to the sun, and 3 to the center of the earth. The velocity definition (column 79) indicates whether the velocities are to be interpreted by the radio ( $v=c \Delta f / f_{0}$ ) (1) or optical ( $v=c \Delta \lambda / \lambda_{0}$ ) (2) definition.

Each " S " card could have its own velocity and inversion indicators, noise tube temperature, rest frequency, and/or center frequency formula depending on how the receiver is divided to observe different lines or velocity ranges with one or more receiver frontend channels.

### 9.2. FEED OFFSET CARD: "F" CARD

The feed offset card, or "F" card, specifies positions of beams in multi-feed systems with respect to the axis of receiver box rotation in polar coordinates, $\rho$ and $\theta$. These are in decimal degrees with $\theta$ measured eastward from north when the box is at zero rotation angle as indicated at the control console. The sole purpose of the " $F$ " card is to provide beam position information to the off-line programs via the telescope tape header. It has no effect on the actual position of the receiver on the telescope. Table 9-2 shows the " $F$ " card format along with nominal feed offsets for multi-feed receivers currently in use on the 300 foot. Trailing zeroes must be punched on the "F" card.

### 9.3. TRAVELLING FEED RECEIVER OFFSETS: "B" CARD

The travelling feed box ( $0.3-1 \mathrm{GHz}$ ) allows two feeds to be installed for observations at $300-500 \mathrm{MHz}$ or $500-700 \mathrm{MHz}$, and $700-$ 1000 MHz . The two feeds are physically offset from center by $\pm 34$ inches, so that the whole box must be moved to get either feed on axis. The 300-700 MHz receiver is located East on the box ( -34 inches), and the $700-1000 \mathrm{MHz}$ receiver is located West on the box (+34 inches). These offsets are entered on $a$ " $B$ " card in the observer's setup deck for the DDP116 computer, which passes the value to the H316. The "B" card format is shown in Table 9-3.

### 9.4. AUTOMATIC L.0. CARD: "L" CARD

The automatic local oscillator "L" card is used to specify Model III autocorrelator and synthesizer settings. Autocorrelator settings must be done manually by the operator and are only checked against the contents of the " $L$ " card. Data taking cannot start until all autocorrelator checks are satisfied. If the observer chooses, the L.O. synthesizer can be under computer control. If there is an "L" card in the DDP116 deck, then the program demands that the L.O. be in computer control. In automatic control the synthesizer settings on the "L" card are recorded on tape. The " $L$ " cards go in the source card sequence, and each card controls receiver settings for all subsequent source cards until another "L" card is encountered.

There are 3 modes of L.O. control. In Mode l, L.O. settings are made by commanding the ULO frequency $F_{0}$ directly. In Mode 2 , the center frequency in the source frame of reference is specified. The choice of reference frame is taken from the " $S$ " card, and there is no provision for velocity offsets. In Mode 3, the center of the band is set to a commanded velocity in the source frame of reference. The rest frequency and choice of reference frame are taken from the "S" card. In Modes 2 and 3, Doppler corrections are made in the transformation between the chosen frame of reference and the telescope frame; L.0. settings are updated every 10 seconds to track the changing Doppler corrections. In all three modes, the $L .0$. settings for the two reference frequency bands are computed from commanded offsets from the center of the observed band. That is, if the observer wishes the center of the reference band
to be 1 MHz higher than the signal band, then the offset should be set to 1 MHz , without worrying about multipliers or Doppler corrections.

The three card formats for " $L$ " cards are shown in Table 9-4. Many of the parameters are codes, elaborated upon in the notes to Table 9-4. In mode 3, columns 4-17 are often used for a descriptive comment. These columns are not read by the program. Nearly all operations use only one L.O., so column 2 usually contains a 1 . A separate card would be used for each of multiple L.O.'s. $F_{0}$ is the primary L.O. frequency (first receiver L.0. frequency divided by the multipliers, i.e. the frequency synthesizer output), and $F_{\text {ref }}$ and $F_{\text {ref }}$ are the frequency offsets used in frequency switching. ref In modes 2 and 3 the reference frequencies are derived by applying specified offsets to the calculated $F_{0} . F_{0}$ is normally in the 250 to 500 MHz range. LA through LD are the FF values set into the IF processor rack. The IF frequencies should be entered with a sign to indicate the desired sideband of the L.0. frequency to be observed. A positive IF is specified if the L.O. is below the sky frequency (upper sideband). The front end switch indicator (column 77) only has effect if a switch (such as a Dicke switch) in the front end is being controlled by the autocorrelator. Otherwise this number may be any of those allowed in note 4. The standard time mode is one of three preset autocorrelator duty cycles available if front panel control is not assumed. The switch rate and duty cycle refer to a switched receiver system (SPOWR3 or MPOWR3). The duty cycle is the signal time to reference time proportion. Time mode 3 , with a $90 / 10$ duty cycle, is usually used only when an average of many reference spectra is going to be taken off-line. In note 5 to Table $9-4$, DT is the dump time, BT is the blanking time to suppress switching transients, for which 10 milliseconds is often sufficient, $S T$ and $R T$ are signal and reference times, and C/D is the number of switching cycles per correlator dump. With an unswitched system (TPOWR3), time mode 1 is always used.

The automatic L.O. system provides continuous frequency counter checking of the synthesizer output and IF frequencies to be sure that they agree with the specified frequencies on the "L" card. During scans, the synthesizer output frequencies are averaged over each integration period and then checked. Between scans they are averaged for 10 seconds, and then checked. If a discrepancy between frequencies or excessive jitter between successive measurements is detected, the result is a ULO error. ULO error messages are printed on the teletype when encountered. Data taking continues in spite of a ULO error. A twodigit code is used and can be cross-referenced to the codes found in Table 9-5.

### 9.5. UP-CONVERTER RECEIVER L.O. CONTROL: "E" CARD

Most receivers at the 300 foot can be treated as single conversion (one L.O. and one IF) systems where the simple frequency equation

$$
\begin{equation*}
F_{\text {sky }}=F_{0} * M * N+I F \tag{9-1}
\end{equation*}
$$

is assumed by the computer in the L.O. computations. However, this is
not the case with receivers incorporating up-converters, so provision has been made through an "E" card to specify constants in the following equation to be used by the computer:

$$
\begin{equation*}
F_{0}=D *\left(F_{\text {sky }}-(C+E * L A+F * L B)\right) /(M * N) \tag{9-2}
\end{equation*}
$$

where $M$ and $N$ are specified on the " $S$ " card. The " $E$ " card enters values for $C, D, E$, and $F$ through the format shown in Table 9-6.

The "E" card could be entered at any time, but would normally go into the DDP116 with the " S " and " F " cards. If no " E " card is read after the on-line program is loaded, default values of $C=0, D=+1, E$ $=+1$, and $F=0$ are assumed. This reduces the L.0. equation to the simpler single conversion receiver equation, equation (9-1). Once an "E" card is entered, the default values are lost until the on-line program is reinitialized. As an example, if the following values were entered: $C=812500, D=+1, E=-1$ and $F=0, M=4$ and $N=1$, the equation would read:

$$
\begin{equation*}
\mathrm{F}_{0}=\left(\mathrm{F}_{\text {sky }}-3250 \mathrm{MHz}-\mathrm{LA}\right) / 4 \tag{9-3}
\end{equation*}
$$

The "E" card would have no effect on the operation of a mode 1 " L " card.
If the observer chooses the L.O. frequency can still be set manually by switching the synthesizer out of computer control. In this case and "L" card is not used, and the frequency recorded on tape is the checking counter value, which has an accuracy of $\pm 100 \mathrm{~Hz}$.

### 9.6. SOURCE CARDS

Besides the telescope positioning and scheduling information on the source cards, described in Chapter 8, there is only one additional parameter connected with spectral line programs. When making total power observations (TPOWR3), a scan will automatically be flagged as an "off" or reference scan if a " 1 " is punched in source card column 57. A command in the POPS data analysis program (FETCH) will look back through the data to find the most recent scan flagged as an "off" before the "on" that it simultaneously loads into the work areas. For this reason, analysis is somewhat simplified if the "off" for a particular object is obtained before the "on" scan.

Observers are hereby reminded for the last time about the timing requirements imposed by computer-autocorrelator timing idiosyncrasies, as described on page 9-2.

### 9.7. ON-LINE DATA REDUCTION

The on-line MODCOMP analysis computer is available to the observer during the course of scheduled observations. Although data from all programs is recorded on 9 -track telescope tapes for off-line reduction, the data are simultaneously transmitted from the DDP116 to the MODCOMP for inspection and reduction. The On-site Spectral Line Data Reduction
manual contains the information necessary to use the POPS analysis program, and that information is not repeated here.

Data records received from the DDP116 are accumulated to form a single spectrum for each receiver in each scan. This accumulated scan is stored on a disk associated with the analysis system. The total number of scans that can be held on disk is 2560 . When the disk storage area is full, storage "wraps around" so that the most recent scan overwrites the data at the front of the area. It is useful to estimate how often the disk will fill up in those cases where the observer is trying to reduce all of the data on-line so that no data is overwritten before it is reduced. It is not a disaster if some data is overwritten, but the procedure for recovering from this situation is somewhat cumbersome. The recovery procedure involves reading the telescope tape onto the MODCOMP in the Jansky Lab, which is a clone of the one at the telescope, and completing reduction on that computer.

The KEEP area on disk and KEEP tapes are a way to store and transport reduced or partially reduced scans, in contrast to telescope tapes, which record raw data record by record. The KEEP command in POPS is fully described in the POPS manual. Basically, the POPS analysis program can read data from a disk area for processing. An auxiliary disk area, the KEEP area, can be written sequentially from POPS. The KEEP area can be used to store completely reduced data, intermediate steps, partial averages, or simply to keep only scans instead of individual records. The KEEP area can be dumped onto a tape and subsequently read into the data file for further processing. The KEEP area can hold 143 scans, and must be dumped to tape when it is full. The KEEP tape format can be found in the POPS manual.

### 9.8. OFF-LINE DATA REDUCTION

The standard NRAO spectral line data reduction programs are completely described in the TPOWER-SPOWER manual so they will not be discussed here. It may be useful, however, to briefly describe the information on tape and the steps taken in doing the basic spectral scaling. For one reason or another, the observer may want to do some or all of the data handling, but in any case the procedures involved should be understood.

Tables A-1, A-2, A-3 of Appendix A give the 9-track telescope tape formats for MPOWR3, SPOWR3, and TPOWR3, respectively. The various word formats are also described. The observer can read the 9-track telescope tape with his or her own program, read the 9-track user tape generated by the IBM TPOWER/SPOWER programs as described in their manual, or read the 9 -track telescope tape back into the analysis system in the Jansky Lab. The instructions for starting up the Jansky Lab analysis computer are taped to the front of the unit. The telescope tape may be loaded by typing the following commands:

Then the POPS program can be invoked just as at the telescope. For observers writing their own programs, once the word formats are understood, the interpretation of the time and position information in the tape record is fairly straightforward. The calculations required to interpret the spectral numbers were described in Chapter 6. Telescope tapes and KEEP tapes are usually written at 1600 BPI , but the MODCOMP can produce 800 BPI tapes if desired.

Figure 9-1. Sample DDP116 input card deck for spectral line observing. This deck is for observing HI in galaxies in total power, using " $L$ " cards to set up the receiver for the velocity of each galaxy. The setup changes from two receivers for galaxies with known redshifts to four receivers with different IF frequencies to search for galaxies with unknown redshifts. The receiver changes are actually made manually by the telescope operator and checked by the computer.

## 10. CONTINUUM OBSERVING

10.1. OBSERVING PROGRAMS

The purpose of this chapter is to describe the on-line computer programs for continuum observing that run on the DDP116 computer, and the setup cards necessary to use them. The setup cards contain information that the computer uses to sample the correct analog-to-digital converters, to calibrate the data, and to command the L.0. system. The card input to the DDP116 computer consists of setup cards followed by source cards. Besides the telescope pointing and scheduling information on the source cards discussed in Chapter 8, there are a few additional parameters on source cards for continuum observing. This section gives a general description of the on-line observing programs.

For moderate sampling rates, the choice of observing program is governed by a decision to use the "standard" continuum receiver or the digital continuum receiver (DCR). The square law detectors in the autocorrelator are also used for continuum observations intended to calibrate line observations. The continuum receivers are described in Chapter 5, where it is pointed out that the "standard" designation should simply be read as "analog", to contrast it with the digital receiver. The digital receiver is equally "standard" in the sense of being used routinely. The program for the standard continuum receiver is called CONDAR. The program for the digital receiver is CONINT. The setup cards for the two programs are identical, but since many parameters are entered manually into the digital receiver, a number of fields in the setup cards are ignored in CONINT. The calibration modes are somewhat different between the two receivers. Data from the digital receiver are received by the DDP116 computer as already calibrated numbers. Data from the standard receiver are received as arbitrary units which must be calibrated in a later stage of analysis, which requires somewhat more care to make sure that there are enough measurements of the internal noise source to stabilize against gain fluctuations.

A fast-sampling program, FSAMP2, is intended for high data rates, such as in pulsar observations. 1, 2, or 4 receiver channels can be sampled at a 1 sidereal millisecond rate. 1, 2, 4, or 8 receiver channels can be sampled at multiples of 5 sidereal milliseconds. A large amount of computer tape is used by this program. At the 1 ms sampling rate a $2400^{\prime}$ tape lasts about 15 minutes, so arrangements should be made well in advance if more than 3 or 4 tapes are to be consumed. In the past, program FS6 was available for sampling 50 channels at a 30 millisecond rate, but it has fallen into disuse and is no longer maintained. A special effort on the part of the Green Bank programmers would be required to resurrect it, so the computer division should be contacted before considering its use. Also, there are no standard off-1ine programs for handling data from FSAMP2 or FS6, so observers should generally expect to provide their own data reduction programs. To assist this effort, 9-track telescope tape formats are given in Appendix A.

A 4096 channel Fabri-Tek signal averager is available for use at the 300 foot for synchronously integrating repetitive signals such as
those from pulsars. The complexity and variety of timing and synchronization schemes employable with this system are beyond the scope of this manual, however. There is an on-line program, SAVG2, which will record data sent from the signal averager onto a 9-track tape. Once a scan is initiated by an observing card, the signal averager controls the integration times and data transfers. The details of the electronics setup at the telescope for this type of program have been the result of close cooperation between pulsar observers and the Green Bank electronics staff. New observers should plan on considerable preparation before the observing begins. No standard off-line programs are supported for the signal averager tapes.

In spite of the differences between observing programs, the setup cards required are basically similar, and so this chapter is organized by type of card rather than by program, except for the first section, which discusses the difference between calibration modes of CONDAR and CONINT. The emphasis of this chapter is on the basic programs CONDAR and CONINT.

### 10.2. GAIN STABILIZATION AND CALIBRATION

The Digital Continuum Receiver Manual [57] contains a discussion of sources of unwanted signals in continuum observations, and various schemes for minimizing them. Parts of that discussion will be summarized in this section. The digital continuum receiver is quite flexible in terms of calibration and switching modes, but the standard continuum receiver is less flexible, and the available calibration modes for the standard receiver are also discussed. Although gain stabilization and gain calibration are separate problems, as discussed in the DCR manual, both topics are jumbled together in this section.

If receiver/detector systems were stable enough, continuum observations would be made in the total power mode, where the output of the detector is simply sampled during an observation, and calibration is done before or after the observation. No calibration noise source degrades the system temperature or decreases the integration time during an observation in the total power mode, making this the most sensitive observing technique, in principle. This technique has been seldom used 4 however, because it relies on a total system stability of a part in $10^{4}$ or better over time scales of an observation, typically a minute or more. On the other hand, receivers are more stable now that GaAsFET amplifiers are replacing parametric amplifiers, so total power observing should at least be considered, particularly for fast scanning of small sources. Programs to measure the fluxes of moderately strong ( 1 Jy ) point sources with total power drift scans have been performed successfully at the 300 foot with certain receivers.

Both digital and standard continum receivers can operate in the total power mode. The digital receiver automatically computes the gain and system temperature between scans, and applies the last measured values to the data during a scan, sending calibrated data to the computer. With the standard receiver, the CONDAR program makes provision for specifying a timed cal scan, which is a separate calibration scan. The
parameters of a timed cal scan are set at the control panel. In the on-line analysis program, the calibration factors derived from a timed cal scan are applied to all subsequent total power scans until another timed cal scan is run.

Assuming that receivers and properties of the telescope/feed combination are not sufficiently stable to measure weak radio sources in the total power mode, a number of switching and gain stabilization schemes have been devised. As discussed more extensively in the DCR manual [57], different observing conditions call for different stabilization methods. For example, beam switching is commonly used for continuum observations above 3 GHz to compensate for atmospheric fluctuations. The other basic stabilization schemes are load switching and noise adding radiometry (NAR).

In noise adding radiometry, a strong noise signal is periodically injected into the receiver input, and the receiver output is integrated in signal and reference integrators, which are connected to the detector in synchronism with the noise source being off and on, respectively. The radiometer output is proportional to the signal integrator divided by the reference minus signal difference. The advantage of NAR over load or beam switching is that a lossy switch does not have to be put in the signal path ahead of the low noise amplifier. A disadvantage is that NAR only compensates for receiver gain fluctuations and does not cancel changes in receiver or sky noise temperature. If possible, the noise switching frequency should be faster than any gain instabilities in the receiver. If this is not possible, the switching frequency should at least avoid any narrowband features in the receiver's postdetection spectrum, such at the 1.2 Hz feature associated with the refrigeration systems used on NRAO receivers and the 60 Hz power line feature.

The maximum sensitivity NAR has a very strong noise source and spends about equal times on signal and reference. The DCR is programmed to provide equal signal and reference integration times for sensitive observations. Program CONDAR for the standard continuum receiver has a somewhat limited form of NAR conveniently provided for in a mode referred to as pulsed cal. In the pulsed cal mode, the calibration noise soyrce is turned on every $15^{\text {th }}$ integration period, beginning with the $3^{\text {rd }}$. The on-line analysis computer uses two integrations on each side of this noise spike as a baseline for the reference minus signal difference, and simply averages all of these differences, computing a single calibration factor for an entire scan, so the gain is no more stable than in total power. However, the calibration may be more accurate, as well as more convenient, since it is made during the actual observations rather than before or after. An observer could provide a more sophisticated analysis program but it would have to involve reading the 9-track telescope tape. In the pulsed cal mode, program CONDAR imposes 0.2 of blanking time at the beginning and end of the calibration period, and so the pulsed cal mode cannot be used with integration times shorter than 0.6 .

Load switching is one of the oldest methods of receiver stabilization in radio astronomy, and is often called Dicke switching after one
of its first users, R.H. Dicke. As the name implies, the receiver input is switched between the antenna feed and a stable resistive load. The radiometer output is the difference between signal and reference integrators. Immunity from gain fluctuations depends on a balance between signal and reference levels in their respective integrators. In the DCR this can be accomplished by a multiplicative factor applied to the reference integrator count. In the analog system, an attenuator would have to be switched into the reference path ahead of the synchronous detector. One penalty of using gain modulation to compensate for unequal reference and antenna temperatures is that the system will respond to variations in the noise temperature of the receiver behind the load switch in proportion to the compensating gain imbalance. In the worst case of a very hot reference load, any receiver temperature variation would show up as an equivalent synchronous detector output signal. Normally the gain imbalance is not required to be so severe, and receiver temperature is usually more stable than receiver gain. For some radiometers incorporating the DCR, balancing is accomplished manually by setting a fixed signal-to-reference ratio in the calculator. Radiometers which are automatically balanced by the DCR retain the signal-to-reference ratio measured just before a scan begins for the duration of that scan. The synchronous detector in the standard analog receiver is balanced manually.

In beam switching the receiver gain variation immunity advantages of load switching plus substantial cancellation of atmospheric noise fluctuations can be achieved by replacing the reference load with an offset antenna beam. Since the noise received by the front end will be very nearly equal in the signal and reference halves of the switch cycle the system is intrinsically nearly balanced. However, there are two sometimes conflicting balance conditions in a beam switched radiometer. To cancel atmospheric fluctuations, the amount of power received from the atmosphere in the general direction of the main beam should be the same in the signal and reference beams. If there were higher resistive or reflective losses in the reference beam path than in the signal beam path, the gain would want to be increased in the reference half-cycle to compensate for the loss in atmospheric noise power. On the other hand, higher resistive losses in the reference path would produce a higher noise input to the front end which would call for a gain reduction in the reference half-cycle to maintain receiver gain fluctuation immunity. One way around this conflict is to balance the gain for equal power from the atmosphere and balance the noise input level by adding noise or resistive attenuation to the signal beam path. However, it is often difficult to decide when the atmospheric noise contribution is equal in the two halves of the switch cycle.

To summarize the gain stabilization discussion, total power observing should be considered as a possibility with the newer receivers. If total power observing is not feasible, then beam switching is desirable at the higher frequencies, if multiple feed receivers are available, to reduce the effect of atmospheric fluctuations. NAR and load switching are available for single feed receivers. In the standard analog receiver setup, these switching schemes require a synchronous detector to be balanced manually and sampled by the DDP116 computer. Using the DCR as a digital synchronous detector, automatic balancing is available in some
setups. The $D C R$ is rather more flexible in setting up a gain stabilization scheme, and has the advantage that its integrators are ideal integrators rather than RC integrators with a finite time constant.

To summarize the gain calibration discussion, gain calibration with the DCR is necessarily but automatically taken care of as data is acquired and before data is passed to the DDP116 computer. Further processing is possible in some switched modes by passing continuously computed gain data to the DDP116 for recording on tape. On the other hand, observations with the standard analog receiver are calibrated in the on-line analysis computer or off-line. In this case one must keep in mind that the only monitor of system performance may be the calibrations specifically invoked and recorded on tape. The calibrations must therefore be frequent enough to correct for receiver instabilities and readjustments. For this reason, and the fact that the data reduction is somewhat simplified, the pulsed cal mode is most frequently used, where possible. The alternative is to run a separate timed cal scan, preferably before an observation rather than after, for convenience in analysis, and before and after for accuracy.

### 10.3. SETUP CARDS: "S" CARDS

For the continuum programs, the setup cards are used to specify the channels in the analog-to-digital converter to be sampled and to pass along some information to the automatic L.0. and the off-line programs by way of the tape header. There must be one " $S$ " card for each receiver channel.

The "S" card format for CONDAR and CONINT is shown in Table 10-1. Column 31 contains an "X" on the first card only and is blank on all others. The first channel to be read from the analog-to-digital converter is identified in columns 32-33, with these columns blank on subsequent " $S$ " cards. All of the channels to be read must be in a continuous sequence, and the number to be read is controlled by the number of " $S$ " cards (up to 8). The observer should consult the receiver engineer in charge or the receiver installation sheet to be certain which channels the receiver is connected to. "S" card data is associated with the $A / D$ channels in the order of the cards in the setup deck, i.e. the data on the second "S" card are associated with the A/D channel immediately following that specified on the first "S" card. Since there is no numbering on the cards, it is important not to shuffie the "S" cards in the input deck. Sample setup decks for CONDAR or CONINT are shown in Figure 10-1.

The declination pointing coefficient identifier (see Section 8.1.2 and Table 8-3) is punched in columns 6 and 7 . This code enables the H316 computer to select the proper coefficients in the decination pointing equations for the receiver in use. The pointing code (columns 34-35) specifies which of the beam offsets on the feed offset card ("F" card) apply to the channel represented by the "S" card. The observing wavelength in centimeters (columns $36-39$ ) is used by the off-line programs to scale the beam offsets in beamwidths. The noise source value (columns 40-45) is used to apply a calibration to the data off-
line or in the on-line analysis computer. A decimal point must be punched in column 43.

If the digital continuum receiver is being used, then the $A / D$ channel information and noise source values on the " S " cards are ignored, and must be entered manually at the calculator keyboard.

The information on the setup cards for FSAMP2 is basically the same as on those for CONDAR and CONINT, except that the observing wavelength is omitted. The " S " card format for FSAMP2 is given in Table 10-2. A decimal point must be punched in column 39.

Only one setup card is needed for program SAVG2, and the only things it contains are an " $S$ " in column 1, the observer name(s) in columns 11-30, and the synthesizer and front end multipliers as shown in Table 10-3.

> 10.4. FEED OFFSET CARD: "F" CARD

The feed offset card, or " F " card, specifies positions of beams in multi-feed systems with respect to the axis of receiver box rotation in polar coordinates, $\rho$ and $\theta$. These are in decimal degrees with $\theta$ measured eastward from north when the box is at zero rotation angle as indicated at the control console. The sole purpose of the " $F$ " card is to provide beam position information to the off-line programs via the telescope tape header. It has no effect on the actual position of the receiver on the telescope. Table 10-4 shows the " F " card format along with nominal feed offsets for multi-feed receivers currently in use on the 300 foot. Trailing zeroes must be punched on the "F" card.

### 10.5. TRAVELLING FEED RECEIVER OFFSETS: "B" CARD

The travelling feed box ( $0.3-1 \mathrm{GHz}$ ) allows two feeds to be installed for observations at $300-500 \mathrm{MHz}$ or $500-700 \mathrm{MHz}$, and $700-$ 1000 MHz . The two feeds are physically offset from center by $\pm 34$ inches, so that the whole box must be moved to get either feed on axis. The $300-700 \mathrm{MHz}$ receiver is located East on the box ( -34 inches), and the $700-1000 \mathrm{MHz}$ receiver is located West on the box (+34 inches). These offsets are entered on a " $B$ " card in the observer's setup deck for the DDP116 computer, which passes the value to the H316. The "B" card format is shown in Table 10-5.

### 10.6. AUTOMATIC L.0. CARD: "L" CARD

With most continuum observations, only one L.O. frequency is used during an entire run, with the L.0. settings made in the manual mode. However, automatic L.O. control is available through an "L" card similar to the mode 1 card described in Section 9.4. In this mode, frequency synthesizer settings are specified directly. The use of an "L" card may be desirable, even in the manual setting mode, to minimize the chance of a discrepancy between desired and actual synthesizer settings. The
format for the continuum "L" card is shown in Table 10-6. FREF 1 and FREF 2 (columns 19-39) usually have no use in a continuum program. F is the frequency synthesizer setting and is calculated from the desired sky frequency and the L.O. multipliers $M$ and $N$, taken from the " $S$ " cards. In CONDAR and CONINT, $F_{\text {. }}$ is continuously checked with a frequency counter to see that the synthesizer output agrees with the specified value. A discrepancy results in a ULO error message at the DDP116 teletype, but data taking is not affected. ULO error codes and their meanings are listed in Table 9-5. In the fast sampling program FSAMP2 and the signal averager program SAVG2 there is no frequency checking. In the fast sampling program FSAMP2 there cannot be an "L" card. The presence of an " $L$ " card in the input deck will result in an error. Programs CONDAR and CONINT will support the presence of an "E" card, to allow automatic setting of the L.0. for up-converter receivers. The "E" card is very rarely used in continuum programs, and so the discussion of the "E" card in Section 9.5 and Table $9-6$ is not repeated in this chapter.

### 10.7. SOURCE CARDS

Besides the telescope pointing and scheduling information on the source cards described in Chapter 8, there are a few additional parameters pertinent to continuum observations.

In CONDAR, the pulsed cal calibration mode is invoked by a blank or " 0 " in source card column 54. This causes the calibration noise source to be turned on every $15^{\text {th }}$ integration period beginning with the third. Since there is 0.2 of blanking time at the beginning and the end of the calibration period, the timed cal mode cannot be used with integration times less that 0.6 . The timed cal mode is invoked by a " 1 " in column 54. This is a single shot calibration sequence, the total duration of which is set on the telescope control console. If, for example, a $30^{s}$ timed cal duration is set with a 1.0 integration time, the computer will start taking data with the noise source off at the start time on the observing card. After $15^{\mathrm{s}}$ the noise source will be turned on for $30^{\mathrm{s}}$, then off again for $15^{\mathrm{s}}$, at which time the scan will end even if the stop time has not been encountered. A separate source card must be used for the timed calibration. It is convenient to run a timed cal scan before a total power scan. The total power mode, with no calibration superposed on the data, is invoked by a 2 in source card column 54. The console switch for calibration has no effect in card control except that it cannot be left in the MANUAL position.

Data taking by the continuum programs can be delayed until the position error in declination is less than 20 arcseconds by placing a " 1 " in column 56.

### 10.8. ON-LINE DATA REDUCTION

The on-line MODCOMP analysis computer is available to the observer during the course of scheduled observations. Although data from all programs is recorded on 9 -track telescope tapes for off-line reduction,
the data are simultaneously transmitted from the DDP116 computer to the MODCOMP for inspection and reduction. The program for analyzing data is CONDAR, which is completely described in a separate manual. The data retrieval and data manipulation is very much the same as it is in POPS, the spectral line analysis program.

The number of data points in a continuum scan depends on the sample rate and the scan length, and is arbitrary. However, there is a maximum number of data points transferred from the DDP116 computer to the MODCOMP in a single scan. The maximum number of data points is 1190 . This amounts to $19^{\mathrm{m}} 50^{\mathrm{s}}$ at a 1 Hz sample rate. All of the data is recorded on tape, but only this number of points can be examined online. The analysis disk can hold 1560 continuum scans of this maximum length, and more if the scans have fewer points. When the disk storage area is full, storage "wraps around" so that the most recent scan overwrites the data at the front of the area. It is useful to estimate how often the disk will fill up in those cases where the observer is trying to reduce all of the data on-line so that no data is overwritten before it is reduced. It is not a disaster if some data is overwritten, but the procedure for recovering from this situation is somewhat cumbersome. The recovery procedure involves reading the telescope tape onto the MODCOMP in the Jansky Lab, which is a clone of the one at the telescope. This may involve recalling tapes from the library in Charlottesville, resulting in further delay.

Data reduced on-line can be saved in a number of ways. Some observers take away only hard copies of scans reduced with their own custom-made procedures, which print all of the desired information on the screen. The parameters of Gaussian fits to the data can be stored at the end of a disk area set aside for that purpose by invoking the GPUNCH verb in CONDAR. This area can be copied onto a tape. A program in Charlottesville will take such a tape and produce punched cards for the observers' own reduction programs. Processed scans themselves can be saved on a KEEP tape for transport to the off-line analysis system in the Jansky Lab or elsewhere. The KEEP area on disk and KEEP tapes are a way to store and transport reduced or partially reduced scans, in contrast to telescope tapes, which record raw data record by record. The KEEP command in CONDAR is fully described in the CONDAR manual. Basically, the CONDAR analysis program can read data from a disk area for processing. An auxiliary disk area, the KEEP area, can be written sequentially from CONDAR. The KEEP area can be used to store completely reduced data, intermediate steps, partial averages, or simply to keep only scans instead of individual records. The KEEP area can be dumped onto a tape and subsequently read into the data file for further processing. The KEEP area can hold 143 scans, and must be dumped to tape when it is full. The KEEP tape format can be found in the CONDAR manual.

Only CONDAR/CONINT data can be examined by the CONDAR analysis program. There are no supported programs -- on-line or off-line -- for the analysis of FSAMP2 or SAVG2 data.

### 10.9. OFF-LINE DATA REDUCTION

A continuum data reduction system called CONDARE is available for use on the IBM 4341 computer in Charlottesville. This system is described in its own manual. For observers who would like to work directly with the telescope tapes, the formats for tapes written by CONDAR, CONINT, FSAMP2, and SAVG2 are given in Appendix A. No matter how the data are reduced, consider the fact that the receiver outputs written on tape by CONDAR, FSAMP2, and SAVG2 are in arbitrary units, and some reference calibrations must also be put on the same tape. Since the output of the $A / D$ converters contains fewer bits than a computer word, the data words are padded out so that the least significant bit is zero when the calibration noise source is off, and one when the calibration noise source is on. Of course the data written on tape by CONINT is already calibrated. Telescope tapes are normally written at 1600 BPI but the MODCOMP can also write 800 BPI tapes, if desired.

## APPENDIX A

## NINE-TRACK TELESCOPE TAPE FORMATS

For the benefit of observers who choose to or must write their own data reduction programs, the 9 -track telescope tape formats are given in this appendix. The individual word formats are described after the last tape format table, and notes unique to particular data groups are included with each tape format. As new features are added to the on-1ine programs, It may be necessary to change tape formats, so the programmer should be sure he has the latest one. Hopefully, they will not have to be changed more than once every year or two.

TABLE A-1
FORMAT 55, MPOWR3

| WORD | FORMAT | CONTENTS |

| 15-16 | 5BB30 | LD | I.F. Offisets |
| 17-18 | 5BB30 | L2 | Second L.0. Data |
| 19-20 | 5BB30 | L2F1 | Second L.0. Data |
| 21-22 | 5BB30 | L2F2 | Second L.0. Data |
| 23 | 2B15 | M2 | Second L.0. Data |
| 24 | 2B15 | N2 | Second L.0. Data |
| 25-26 | 5BB30 | L3 | Third L.O. Data |
| 27-28 | 5BB30 | L3F1 | Third L.0. Data |
| 29-30 | 5BB30 | L3F2 | Third L.0. Data |
| 31 | 2B15 | M3 | Third L.O. Data |
| 32 | 2B15 | N3 | Third L.0. Data |

3. 384 channels of relative spectral intensities are contained here. In MPOWR3 and SPOWR3 the set of signal channels appear first followed by 384 reference channels. The spectral intensities in MPOWR 3 are contained in single 16 bit interger words. In SPOWR3 and TPOWR3, however, 2-16 bit words are used in series and must be combined off-line to produce a $32-b i t$ integer. (See the sample program.)
4. The power counters are integrated for the period of time indicated in word 33. They are recorded in the same order as A/C words 770-785 and 1556-1571 as described in Appendix I of ref. [31].
5. See Appendix I of ref. [31] for the order and format of these words.

## Layout of Words 55-1078

This layout varies according to the number of channels being recorded. The table below illustrates the variation. The entries give the channel number and the sample number.

| WORD | 1 Channel Recording | 2 Channe 1 Recording | 4 Channel <br> Recording | 8 Channel Recording |
| :---: | :---: | :---: | :---: | :---: |
| 55 | 1/1 | 1/1 | 1/1 | 1/1 |
| 56 | 1/2 | 2/1 | 2/1 | 2/1 |
| 57 | 1/3 | 1/2 | 3/1 | 3/1 |
| 58 | 1/4 | 2/2 | 4/1 | 4/1 |
| 59 | 1/5 | 1/3 | 1/2 | 5/1 |
| 60 | 1/6 | 2/3 | 2/2 | 6/1 |
| 61 | 1/7 | 1/4 | 3/2 | 7/1 |
| 62 | 1/8 | 2/4 | 4/2 | 8/1 |
| 63 | 1/9 | 1/5 | 1/3 | 1/2 |
| 65 | 1/11 | 1/6 | 3/3 | 3/2 |
| 66 | 1/12 | 2/6 | 4/3 | 4/2 |
|  | - | - | - | - |
|  | - | - |  |  |
|  |  |  |  |  |
| 1075 | 1/1021 | 1/511 | 1/256 | 5/128 |
| 1076 | 1/1022 | 2/511 | 2/256 | 6/128 |
| 1077 | 1/1023 | 1/512 | 3/256 | 7/128 |
| 1078 | 1/1024 | 2/512 | 4/256 | 8/128 |

For example, for 2 channel recording, word 65 contains the sixth sample of the first channel.

The program requires that the number of channels be $1,2,4$ or 8 .

## Word Formats for all Programs

1 - This is an alphanumeric format in ASCII code with two characters per word.

2 - This is a standard 16 -bit integer which ranges from $-32768\left(-2^{15}\right)$ to 32767.

4 - This format is used where double precision is required. It uses 2 16 -bit words in series, the first containing the sign and 15 highest order bits, and the second contains a zero in the sign bit and the 15 low order bits. To handle this in FORTRAN, use the equation

$$
\text { IFOUR }=I D(24) * 32768+\operatorname{ID}(25)
$$

where IFOUR is an INTERGER* 4 word and ID(24) and ID(25) are examples from the MPOWR3 format.

Unless otherwise noted, all of the time and angle measures (e.g. R.A., Dec, E.S.T., L.S.T., and Polarization angle) are in turns time $2^{30}$. To convert the above example into decimal hours, the following statements would be needed:

$$
\begin{aligned}
& \text { REAL*8 C,HLST } \\
& \mathrm{C}=2 . * * 30 \\
& \mathrm{HLST}=\mathrm{DFLOAT}(\text { IFOUR }) / \mathrm{C}
\end{aligned}
$$

Double word spectral values and power counters could best be handled by converting them to REAL*4 since they are only relative numbers and must be used in ratios.

5 - These are also sets of double 16-bit words like word format 4, but the decimal may be specified to be anywhere in the bit sequence as specified in the BB--notation. For example, BB17 would indicate that the decimal is 17 places from the left in a 30 -bit word.

For example, to convert the Julian date in the CONDAR format to a decimal number, the following numbers would be required:

$$
\begin{aligned}
& \text { REAL*8 JD, } \mathrm{C} \\
& \mathrm{C}=2 . * * 13 \\
& \mathrm{JD}=\operatorname{DFLOAT}(\operatorname{ID}(20) * 32768+\operatorname{ID}(21)) / \mathrm{C}
\end{aligned}
$$

This could also be done in single precision if all of the accuracy were not required.

By definition, the time and angle measure in word format 4 are BBO.
6 - Same as 5 except that it applies to a single 16 -bit word, i.e. 6BB10 would indicate the decimal is 10 bits from the right of a 16-bit word.

APPENDIX B

## PROGRAM PREP300

VERSION $2.0 \quad 1$ JULY 82
PREVIOUS VERSION SAVED AS 'OLDPREP'

PROGRAM PREP 300 IS USED TO PREPARE OBSERVING CARDS FOR DRIFT SCANS AT THE 3OO-FOOT TELESCOPE. CARDS FOR WOBBLES CAN ALSO BE PRODUCEC. THE PROGRAM CAN PRGDUCE CARDS FOR OBSERVATIONS IN POSITIONING COCES 1-3 ANO 13. CARDS FOR DECLINATION SCANS WITH POSITIONING COCES 3, 8, 13, OR 18 ARE PRODUCED BY A COMPANION program callec point 300. parameters that allow the program to take ACCOUNT OF PRECESSICN, POINTING CORRECTIONS, AND FEED OFFSETS, AS WELL AS THE CHOSEN MODE OF ORSERVING --SCAN LENGTH, INTEGRATION TIME, ETC.-- ARE REAC fRCM THE FIRST EIGHT CARDS ON THE CARD INPUT FILE OR STREAM ISYSINI. THE REST OF THE INPUT CARDS ARE SOURCE CARDS, CONTAINING THE SCURCE NAME ANO 1950.0 RIGHT ASCENSION AND DECLINATICN. THE PROGRAM WILL PUNCH AN CBSERVING CARD IOR PERHAPS MORE THAN CNE CARD) FCR EACH SOURCE.
the cifference eetween this version and the previous version, SAVED AS OLOPREP, IS THE WAY THE DECLINATION POINTING CORRECTION IS IMPLEMENTEC. IN the previous VERSICN a table of CFFSETS TAKING UP TWO INPUT CARDS WAS READ $N$, AND THE PROGRAM INTERPOLATED BETWEEN values in the table. in this versicn, the coefficients of a polyNONIAL FIT ARE REAC FROM A SINGLE CARD. THE OIFFERENCE IN THE NUMBER OF SETUP CAROS BETWEEN THE TWO VERSIONS SHCULD CAUSE A FATAL RUN-TIME ERROR. PREVENTING THE USE CF THE WRONG VERSION.

PROGRAM PREP300 ASSUMES THAT YCU WILL BE DOING ORIFT SCANS. TO SWITCH FROM DRIFT SCANS TO WOBBLES, INSERT A CARD CONTAINING 'WOBBLE IN COLUMNS 1-6 INTO THE INPUT STREAM. TC REVERT BACK TO CRIFT SCANS, INSERT A CARD CONTAINING •ORIFT' IN COLUMNS L-5 INTO THE JJB STREAM. THIS SWITCHING CAN BE PERFORMED ANY NUMBER OF TIMES. DRIFT SCANS ARE OBSERVED WITH A PULSED CAL, AND WOBBLES ARE OBSERVED WITH NC CAL.

PRCGRAM PREP3OO HAS TWO IMPORTANT CONVENIENCE FEATURES: COORDINATE LOOKUP AND DECLINATION OFFSETS. IF THE CONTENTS OF COLUMNS 39-40 ON A SCURCE CARD ARE NOT ZERO II.E. BLANKI THEN THE PROGRAM WILL SCAN THE CONTENTS OF A LOOKUP FILE FOR AN EXACT MATCH to the source name on the card. if a match is found then the PROGRAM USES THE COCRCINATES READ FROM THE DISK FILE. IF NOT. THEN IT USES THE COORCINATES ON THE CARD. THIS PROVIDES A CONVENIENT WAY to use updated ccordinates from the staff maintained lookup file. If the ra and oec fielcs on a source card are blank then the program WILL ALSO LCOK FCR COORDINATES ON THE LOOKUP FILE, BUT IF IT DOES NOT FIND ANY IT PRINTS A MESSAGE AND GOES ON TO THE NEXT SOURCE CARD. A LISTING OF THE CONTENTS OF THE SUPPLIED LOOKUP FILE CAN BE FOUNC IN APPENDIX B OF THE 3OO-FOOT MANUAL.
tre declination offset feature provides a convenient way to OBSERVE THE SAME SCURCE WITH DIFFERENT DECLINATION OFFSETS ON SUCCESSIVE DAYS, UP TC A LIMIT OF 20 DAYS II.E. 20 OFFSETSI. THE NUMBER OF OFFSETS 1141 IS PUNCHED ON INPUT CARD 6 , FOLLOWED BY A LIST OF OFFSETS IN ARCMINUTES (F7.3), WHICH MAY CONTINUE

```
ONTO A SECOND CARD.
    TO RUN PROGRAN PREP3OO YOU SHOULD CREATE A PANDORA MEMBER
CONTAINING IMAGES CF THE INPUT CARDS TO BE READ EY THE PROGRAM, IN
THE FORMATS GIVEN BELOW. AND SAVE IT. THEN CREATE A MEMBER WITH
THE NECESSARY JCL STATEMENTS. IF ALL OF YOUR SCURCES ARE SUPPLIEC
WITH COCRDINATES ON THE SOLRCE CAROS OR CAN BE FOUND IN THE STAFF
MAINTAINED LOOKUP FILES. THEN THE FCLLOWING WILL SUFFICE:
//PREP300 JOB (<USER.t>, 300),\langleYOURNAME>,CLASS=B,MSGLEVEL=(2,0)
/:ROUTE PRINT REMOTEL
/:ROUTE PUNCH REMOTEL
// EXEC PREP300
//SYSIN DD %
TAKE NOTE OF THE TWO SPACES AFTER •ROUTE' DN THE SECOND AND THIRD
CAROS. TO SURMIT THIS JOB, TYPE
SUB <NAME CF JCL MEMBER> <NAME SYSIN MEMBER>
    IF YOU ARE SUPPLYING YOUR OWA LOOKUP FILE, THEN YOU NEED YET
ANOTHER PANDORA MEMBER, OF WHICH THE FIRST LINE IS:
//SOURCES DD :
FOLLOWED BY LINES OF SOURCE NAMES AND POSITIONS IN THE SAME FORMAT
AS FCR SOURCE CARDS. TC SUBMIT THIS JOB, TYPE
SUB <NAME JCL MEMBER> <NAME SYSIN MEMBER> <NAME SOURCES MEMBER>
YOUR LOOKUP FILE WILL BE THE FIRST CNE SEARCHED, RUT IF A SCURCE
IS NOT FOUND THERE, THE SEARCH WILL CONTINUE ON TE THE SUPPLIED
LOOKUP FILE. SCANNING STOPS WHEN A YATCH IS FOUND. SO IF A SOURCE
COULD BE FOUND CN BCTH YOUR LCOKUP FILE AND THE SUPPLIED LOOKUP
fILE, THE PRCGRAM WILL ALWAYS TAKE THE INFORMATICN FROM YOUR FILE.

C
C PROGRAM POINT300

VERSION 2.020 JULY 1982
PRCGRAM POINT 300 IS A CCMPANION PRCGRAM TO PROGRAM PREP300. PROGRAM POINT \(3 C C\) PREPARES OBSERVING CARDS FOR DECLINATION SCANS AT THE 300-FOOT TELESCOPE IN POSITICNING MODES 3. 8. 13. OR 18. SEE PROGRAM PREP 300 FOR MOCES \(1-3\) AND 13 . PROGRAM POINT3OO IS PRIMARILY INTENDED FCR PREPARING OBSERVATIONS TC CHECK THE DECLINATION POINTING CF THE 3OO-FOOT TELESCOPE. THERE ARE RELATIVELY FEW PARAMETERS WHICH CAN BE SPECIFIED BY THE USER, AND THESE ARE READ FRDM THE FIRST TWO CARDS ON THE CARD INPUT FILE THE REMAINING CARDS ON THE CARD INPUT FILE ARE SCURCE CARDS, CONTAINING THE NAME AND 1950.0 COOROINATES OF A SOURCE. TWO OBSERVING CARDS ARE PRODUCED FOR EACH SOURCE CARD: ONE MARKED 'NS' SCANS THE TELESCCPE FROM NORTH TC SCUTH, AND ANOTHER MARKED SN' SCANS FROM SOUTH TC NORTH. THESE PAIRS ARE SEGREGATED INTO TWO SEPARATE OBSERVING DECKS WHICH ARE PRODUCED AT THE END OF THE COMPUTATIONS. THE DECKS ARE FOR USE ON SUCCESSIVE DAYS. IN BOTH DECKS. SUCCESSIVE SCANS ALTERNATE EETWEEN 'NS' AND 'SA' SCANS BUT THE TWC DECKS ARE OUT OF PHASE', ONE GOING NORTH WHERE THE OTHER GOES SDUTH.

PROGRAM PCINT 300 PREPARES CARDS FOR SCANS DRIVEN IN DECLINATION SO THAT THE SOURCE SHOULD PEAK AT THE CENTER OF THE SCAN. FOR THOSE PCSITICNING MCDES IN WHICH THE TELESCCPE IS SIMULTANECUSLY TRACKING IN RIGHT ASCENSION 18 ANO 181 . THE SOURCE SHOULO PEAK AT TRANSIT. ALL OF THE OBSERVING CARDS CONTAIN A CCOE FOR PULSED CAL OBSERVATIONS 10 IN CCLUMN 54). IF A PULSED CAL WOULD OCCUR IN THE LAST OR SECOND TC LAST DATA POINT THE SCAN IS LENGTHENED.

LEAVING THE DECLINATION RATE FIELD ON INPUT CARD 1 BLANK INVOKES THE DEFAULT DECLINATION RATE OF 15 ARCMINUTES PER MINUTE OF TIME. IF THE SECANTI DEC I INDICATOR IS ZERJ THEN THE SCAN RATE IS ALWAYS 15 ARCMIN/MIN, BUT IF THE SECANTI DEC I INOICATOR IS 1 THEN THE SCAN RATE IS SLOWED BY COSI CEC, AND THE SCAN IS LENGTHED BY SECANTI DEC I TO TAKE ADVANTAGE OF THE THE ABILITY OF THE STERLING MOUNTED RECEIVERS TO TRACK A GIVEN RIGHT ASCENSION FGR A LONGER PERIOC OF TIME AT HIGHER DECLINATIONS. THE INTEGRATION PERIOC, OR SAMPLING RATE REMAINS CONSTANT SD THE HIGHER DECLINATION SCANS HAVE MORE DATA POINTS THAN LOW DECLINATION SCANS.

PRCGRAM POINT 300 DOES NOT HAVE THE FEATURE ALLOWING SCANS AT GIVEN OFFSETS FRCM THE NOMINAL SOURCE POSITION, RUT IT DQES HAVE THE SAME COORDINATE LOOKUP FEATURE AS PROGRM PREP300. THAT IS, IF COLUMNS 39-40 ON A SOURCE CARD ARE NOT ZERO II.E. ELANKI THEN THE PROGRAM WILL SCAN THE CONTENTS OF A LOOKUP FILE, LOCKING FOR AN EXACT MATCH TC THE SQURCE NAME ON THE CARD. IF A MATCH IS FCUNC THEN THE PROGRAM USES THE COORDINATES READ FROM THE DISK FILE I IF NOT, IT USES THE COORCINATES CN THE CARD. THIS PROVIDES A CONVENIENT WAY TO USE UPCATEO COOROINATES FROM A MAINTAINED LOOKUP FILE. IF THE RA AND DEC FIELCS ON A SOURCE CARD ARE BLANK THEN THE PROGRAM WILL ALSO SCAN THE LCOKUP FILE, BUT IF IT COES NCT FIND ANY, IT PRINTS A MESSAGE AND GOES ON TO THE NEXT SOURCE CARD.

TC RUN PROGRAM POINT 300 YOU SHCULO CREATE A PANDORA MEMBER CONTAINING IMAGES CF THE INPUT CAROS TO BE READ EY THE PROGRAM．IN THE FORMATS GIVEN BELOW，AND SAVE IT．THEN CREATE A MEMBER WITH THE NECESSARY JCL STATEMENTS．IF ALL OF YOUR SCURCES ARE SUPPLIEC WITH COCRUINATES UN THE SOURCE CARDS OR CAN BE FOUND IN THE STAFF MAINTAINED LCCKUP FILES，THEN THE FCLLOWING WILL SUFFICE：
／／POINT 300 JCE（〈USER\＃〉，300），〈YOURNAME〉，CLASS＝8，MSGLEVEL＝（2，0）
／：ROUTE PRINT REMOTEI
／：ROUTE PUNCH REMOTEL
／／EXEC POINT300
／／SYSIN DO ：
TAKE NOTE OF THE TWO SPACES AFTER＇ROUTE＇ON THE SECOND ANO THIRO CARDS．TO SUBMIT THIS JOB，TYPE

SUB＜NAME OF JCL MEMBER＞＜NAME SYSIN MEMBER＞
IF YOU ARE SUPPLYING YOUR OWN LOOKUP FILE，THEN YOU NEED YET ANOTHER PANDORA MEMBER，OF WHICH THE FIRST LINE IS：
／／SOURCES DO \(\because, D C B=\) ELKSIZE＝80
FOLLOWED BY LINES OF SOURCE NAMES AND POSITIONS IN THE SAME FORMAT AS FCR SOURCE CARDS．TO SUBMIT THIS JOB，TYPE

SUB＜NAME JCL MEMBER＞＜NAME SYSIN MEMBER＞＜NAME SOURCES MEMBER＞
YOUR LOCKUP FILE WILL BE THE FIRST CNE SEARCHED，RUT IF A SOURCE IS NOT FDUNO THERE，THE SEARCH WILL CONTINUE ON TO THE SUPPLIED LOOKUP FILE．SCANNING STOPS WHEN A MATCH IS FOUND，SO IF A SOURCE COULD BE FCUND ON EOTH YOLR LCOKUP FILE AND THE SUPPLIED LOCKUP FILE，THE PROGRAM WILL ALWAYS TAKE THE INFORMATION FROM YOUR FILE．

C
LINE300 VERSION 2．0 20 JULY 1982

PROGRAM LINE 300 PREPARES OBSERVING CARDS FOR SPECTRAL LINE OBSERVATIONS ON THE 3OO－FOOT TELESCOPE IN POSITIONING CODES 8 OR 18．THE PRGGRAM PRODUCES CARDS FOR A SERIES OF SCANS FOR EACH SOURCE，WITH OFF SOURCE SCANS SYMMETRICALLY ARRANGED ABOUT A SINGLE ON SOURCE SCAN．THE NUMEER OF OFF SOURCE SCANS ON EACH SIDE OF THE ON SQURCE SCAN CAN RE SPECIFIED，FOR TOTAL POWER OBSERVING，OR CAN EE SET TO ZERO FCR SWITCHEC POWER OBSERVING．

BESICES THE NUMBER OF OFFS，THE ONLY OESERVING PARAMETERS THAT CAN $\operatorname{SE}$ SET BY THE USER ARE THE POSITIONING CODE AND THE SCAN LENGTH． THE SCAN LENGTH WILL BE ROUNDED DOWN TO A MULTIPLE OF 20 SECONOS TO SATISFY TINING REQUIREMENTS OF THE AUTOCORRELATOR• IF THE SCAN LENGTH FIELC CN A SCURCE CARD IS LEFT BLANK．THEN THE PROGRAM SUPPLIES A DEFAULT SCAN LENGTH CF $240 \div$ SECANTI DEC ，SECCNDS． ROUNDED DOWN TO A MULTIPLE OF 20 SECONDS．THIS IS THE MAXIMUM SCAN LENGTH ALLOWEC BY THE STERLING MOUNT．

THE INTERVAL BETWEEN SCANS IN A SEQUENCE IS 64 SECONDS．THIS IS THE TIME REQUIRED FOR THE STERLING MOUNT TO RETURN TG ITS EAST－ ERNMOST POSITION．THE PROGRAM ALSO ADDS DNE SECCND TO THE SCAN LENGTH TO AVOID A TIMING PECULIARITY BETWEEN THE CORRELATOR AND THE COMPUTER．

PROGRAM LINE 300 SHARES WITH PRCGRAM PREP 300 THE FEATURE OF SCANNING A LOOKUP FILE FOR SOURCE CCORDINATES．THAT IS，IF COLUMNS 39－40 ON A SCURCE CARD ARE NOT ZERO II•E．BLANKI THEN THE PROGRAM WILL SCAN THE CONTENTS CF A LOOKUP FILE LOOKING FOR AN EXACT MATCH TO THE SOURCE NAME ON THE CARD．IF A MATCH IS FOUNO THEN THE PROGRAM USES THE COORDINATES READ FROM THE DISK FILE IF NOT，IT USES THE COORCINATES ON THE CARD．THIS PROVIDES A CCNVEN－ IENT WAY TC USE UPCATED COOROINATES FROM A MAINTAINED LOOKUP FILE． IF THE RA AND OEC FIELDS ON A SOURCE CARD ARE BLANK THEN THE PROGRAM WILL ALSO SCAN TFE LCOKUP FILE，BUT IF IT DOES NOT FIND ANY，IT PRINTS A MESSAGE AND GOES ON TO THE NEXT SOURCE CARD．

TO RUN PROGRAN LINE 300 YOU SHOULD CREATE A PANDORA MEMBER CONTAINING IMAGES CF THE INPUT CARDS TO BE READ EY THE PROGRAM．IN THE FORMATS GIVEN BELOW，AND SAVE IT．THEN CREATE A MEMBER WITH THE NECESSARY JCL STATEMENTS．IF ALL OF YOUR SOURCES ARE SUPPLIEC WITH CCCROINATES ON THE SOURCE CARDS OR CAN EE FDUND IN THE STAFF MAINTAINED LOOKUP FILES，THEN THE FCLLOWING WILL SUFFICE：

EXPECTED PERFORMANCE OF THE $300-1000 \mathrm{MHz}$ RECEIVER ON THE 300 FOOT TRAVELLING FEED

## General

Users should be aware of the expected changes in beam shape and reduced gain caused by the lateral displacement of the feed during normal operation of the tracking mechanism. As the feed is moved off axis, the beam is scanned in the opposite direction. The ratio of the angle of the beam to the angle of the feed measured from the vertex of the antenna is the beam deviation factor. As the beam is scanned, the gain is reduced and the beam is broadened on the side away from the antenna axis. Also, the side lobe level on the axis side of the main beam increases in amplitude.

## Beam Deviation Factor

The beam deviation factor is dependent upon the $f / D$ ratio for the antenna, the the edge illumination provided by the feed, and the displacement off axis [1]. The $300-1000 \mathrm{MHz}$ receiver feeds provide 12 to 15 dB edge illumination. On the 300 -foot the computed beam deviation factor varies from .847 at one foot displacement to . 850 at eleven feet displacement.

## Tracking Range

With the cooled $300-1000 \mathrm{MHz}$ receiver installed, the traveling carriage range is restricted to plus or minus eleven feet. The feeds are offset 34 inches on either side of the center of the carriage. With a beam deviation factor of . 85, the beam angle is 1.89 minutes per inch of travel. The maximum displacement of the feed that is on the side of the box away from the antenna axis would be $132+34$ or 166 inches. This should scan the beam 314 minutes in one direction. The feed on the side of the box toward the antenna axis would have a beam shift of 185 minutes.

The number of half-power beamwidths corresponding to these angular shifts in the beam are tabulated below for 300 and 1000 MHz .

| Frequency | Half <br> Power <br> Beamwidth | Beam Angles |  |
| :---: | :---: | :---: | :---: |
|  | 314 Minutes | 185 Minutes |  |
| 300 MHz | 46.0 minutes | 6.8 HPBW | 4.0 HPBW |
| 1000 MHz | 13.8 minutes | 22.8 HPBW | 13.4 HPBW |

Beam Gain Reduction and Sidelobe Level
The predicted gain reduction is 2 dB at a 6 HPBW beam angle [2]. This value is based on the movement of the feed along a maximum gain curve which
requires increasing the focal distance at larger scan angles. Since the traveling feed movement is restricted to the focal plane, a somewhat larger gain reduction may occur at 6 HPBW . In fact, measurements made with the old tracking feed show 3 dB gain reduction at 6 HPBW .

The sidelobe level (coma lobe) is expected to be only 10 dB below the main beam angles of 4 HPBW [3]. If the usable scanning range is determined to be 4 HPBW , then the tracking range should be limited to:

$$
\begin{aligned}
4 \text { HPBW Tracking Range }= & \pm 29.1 / f_{\mathrm{GHz}} \text { inches }+(\mp 34 \text { " feed offset) } \\
& -63 \text { to }+131 \text { inches at } 300 \mathrm{MHz} \\
& +5 \text { to }+63 \text { inches at } 1 \mathrm{GHz} .
\end{aligned}
$$

## Depolarization Effects

Studies of off-axis-fed paraboloids indicate an increase in the cross-polarization for linearly polarized antennas and beam separation for circularly polarized antennas which increase with offset angle [4]. The maximum traveling feed angular offset of about five degrees may cause some degradation of the polarization properties of the 300 -foot antenna feed system.
