# The Number of Observable Radio Sources for Large Single Telescopes 

S. von Hoerner, UCLA (on leave from NRAO)

## Summary

Future large radio telescopes should reach as far out into space as possible, especially for cosmological studies. For comparing the range of various telescopes we calculate the maximum number $N_{m}$ of observable sources per sky area, and $N_{2}$, the number of sources/area for which the spectrum can be observed through a factor of 2 in wavelength. These calculations are done allowing for future receiver improvement, assuming $40^{\circ}{ }_{K} \mathrm{~K}$ system noise temperature.

The proposed $300-\mathrm{ft}$ homologous telescope will reach $\mathrm{N}_{2}=5.0 \times 10^{4}$ sources/steradian. The NEROC 440-ft reaches $1.5 \times 10^{4}$, the Bonn $100-\mathrm{m}$ telescope $3.2 \times 10^{4}$, and the planned Jodrell Bank 450-ft telescope $0.25 \times 10^{4}$ sources/sterad. Of the existing large telescopes, the NRAO 140-ft reaches $N_{2}=0.81 \times 10^{4}$, the $300-\mathrm{ft} 0.11 \times 10^{4}$, and the Goldstone $210-\mathrm{ft}$ reaches $0.44 \times 10^{4}$. A homologous $410-\mathrm{ft}$ telescope would reach $11.3 \times 10^{4}$ sources/sterad.

These results show again how important it is that future telescopes not only be large, but also be able to observe at short wavelengths. The shortest wavelength $\lambda_{0}$ of the telescope should be smaller than $\lambda_{m}$, the crossing point of resolution limit and brightness limit. We find $\lambda_{m}=2.83 \mathrm{~cm}$ for $D=300 \mathrm{ft}$, 2.58 cm for 410 feet, and 2.45 cm for 500 feet diameter. All proposed homologous telescopes fulfill the condition $\lambda_{0} \leq 0.75 \lambda_{m}$, which means that $N_{2}$ is not resolution-limited.

For cosmological studies one should build a homologous telescope of at least 500 feet diameter, observing down to $\lambda_{0}=1.80 \mathrm{~cm}$ wavelength.

## 1. Assumptions and Formulas

Brightness limit and resolution limit of radio telescopes have been treated in detail (von Hoerner 1961, NRAO Publications Vol. 1, No. 2; in the following called Paper I). At present we give only the basic assumptions and resulting formulas, including a few changes from Paper $I$.

For the brightness limit, we calculate the flux density of the faintest visible source: from Paper I as

$$
S_{\min }=1.70 \times 10^{-5} \frac{T_{0} \sqrt{\lambda}}{g(\lambda)}\left(\frac{300 \mathrm{ft}}{\mathrm{D}}\right)^{2}, \left\lvert\, \begin{align*}
& \mathrm{S} \text { in flux units }  \tag{1}\\
& \mathrm{T} \text { in } \mathrm{o}_{\mathrm{K}} \\
& \lambda \text { in } \mathrm{cm}
\end{align*}\right.
$$

where $T_{0}$ is the overall noise temperature of receiver, spillover, atmosphere and galactic background, $\lambda$ is the observational wavelength, and $g(\lambda)$ is a somewhat arbitrary cutoff function representing slow atmospheric changes or scintillations for small $\lambda$, and man-made noise for large $\lambda$. The numerical factor of (1) assumes a bandwidth of $5 \%$ of the frequency and an integration time of 10 sec (or $1 \%$ and 50 sec , for example).

The cutoff function $g(\lambda)$ assumed in Paper I was much too pessimistic, as observations at 2 cm and below have shown meanwhile. A more realistic but still conservative one is now assumed and is given in Table 1.

For the number of visible sources, we assume a slope of -1.50 for the $\log \mathrm{N} / \log \mathrm{S}$ relation, and we assume that all sources have the average spectrum index of -0.80 . We normalize to the 3 C catalog, and obtain

$$
N_{\text {vis }}=7.84 \times 10^{4} \quad \lambda^{1.2} \quad\left(10^{3} \mathrm{~S}_{\mathrm{min}}\right)^{-1.5} \cdot \left\lvert\, \begin{align*}
& \mathrm{N} \text { in sources/sterad }  \tag{2}\\
& \lambda \text { in } \mathrm{cm} \\
& \mathrm{~S} \text { in flux units }
\end{align*}\right.
$$

For the resolution limit, we calculate $N_{\text {res }}$, the number/sterad of resolvable sources. With respect to fainter background sources we have from Paper I

$$
N_{\text {res }}=9.92 \times 10^{5} \lambda^{-2}(D / 300 \mathrm{ft})^{2} \cdot \quad \left\lvert\, \begin{align*}
& \mathrm{N} \text { in sources/sterad }  \tag{3}\\
& \lambda \text { in } \mathrm{cm}
\end{align*}\right.
$$

Finally, the number of actually observable sources is mostly the smaller one of $\mathrm{N}_{\mathrm{vis}}$ and $\mathrm{N}_{\text {res }}$; but in the neighborhood of their crossing point we must add quadratically the actual noise and the background irregularities, and one can show that, approximately,

$$
\begin{equation*}
N_{\mathrm{obs}}=\left(1 / \mathrm{N}_{\mathrm{res}}+1 / \mathrm{N}_{\mathrm{vis}}\right)^{-1} \tag{4}
\end{equation*}
$$

The maximum number $N_{m}$ then is observed at a wavelength $\lambda_{m}$ approximately given by

$$
\begin{equation*}
\lambda_{\mathrm{m}} \text { where } N_{\text {res }}(\lambda)=N_{\text {vis }}(\lambda) \tag{5}
\end{equation*}
$$

But just barely observing and counting sources is not enough. We should at least be able to observe the spectrum of a source over a range of, say, a factor of 2 in wavelength, in order to measure the spectrum index and to see any stronger curvature of the spectrum. For comparing the range of various telescopes, we thus define $N_{2}$ as the maximum number/steradian of sources which can be observed through a factor of 2 in wavelength.

For this purpose we plot for any given telescope the function $N_{o b s}(\lambda)$ according to (4). Toward small $\lambda$ we cut off at $\lambda_{0}$, the smallest observational wavelength of this telescope. We then find the maximum observable range of length 2 in wavelength, as shown in Fig. 1.

For completely resolution-limited telescopes, we have only

$$
\begin{equation*}
N_{2}=0.25 \mathrm{~N}_{0}, \quad \text { if } \lambda_{0} \geqslant 1.6 \lambda_{\mathrm{m}} ; \tag{6}
\end{equation*}
$$

while it turns out that

$$
\begin{equation*}
N_{2}=0.82 N_{m}, \quad \text { if } \lambda_{0} \leq 0.75 \lambda_{m} . \tag{7}
\end{equation*}
$$

## 2. Applications and Results

For planning future large telescopes, one must somehow take into account the improvement of future receivers to be expected. In Paper I, for example, we find for $D=300 \mathrm{ft}$, with a receiver of $900^{\circ} \mathrm{K}$, that $\lambda_{\mathrm{m}}=14 \mathrm{~cm}$ and $\mathrm{N}_{\mathrm{m}}=$
$3.2 \times 10^{3}$ sources/sterad; whereas a receiver of $20^{\circ} \mathrm{K}$ demands $\lambda_{m}=2.6 \mathrm{~cm}$ and yields $N_{m}=9.1 \times 10^{4}$. This means that future telescopes must be able to observe at very short wavelengths, or they will soon become badly resolution-limited with improving receivers.

For the following we assume a future receiver noise of $25^{\circ} \mathrm{K}$, plus a spillover of $15^{\circ} \mathrm{K}$. Atmospheric and galactic contributions are assumed the same as in Paper I. The resulting overall noise $T_{0}$ is given in Table 1, together with the adopted cutoff function $g(\lambda)$. Then $S_{m i n}, N_{v i s}$ and $N_{\text {res }}$ are calculated as functions of $\lambda$ for a diameter of 300 feet.

Table 1. Brightness and resolution limit, as functions of $\lambda$.

| $\lambda$ | To | $g(\lambda)$ | for $D=300$ feet : |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

| 100 | 85.0 | 1 | 14.4 | 36.0 | . 0099 |

Figure 1 shows the number/sterad of observable radio sources, for the homologous telescopes as suggested in Report 26 (March 1969). In Paper I we have derived that it would be important for cosmological studies to reach
or come close to $N_{m}=3 \times 10^{5}$ sources/sterad; we see from Figure 1 that we should have at least 500 feet diameter for reaching this goas.

For comparison with other proposed or future telescopes we plot Figure 2. For the NEROC telescope we use 440 ft for the resolution limit, and 410 ft for the brightness limit; the Bonn telescope observes at 5 cm for its full size of 100 m , and at 3 cm for its inner part of 90 m diameter. We see from Figure 2 that all these telescopes will be resolution-1imited, at least for future receivers. Especially the proposed Jodrell Bank telescope shows how much is lost if a large telescope does not observe at short wavelengths.

Figure 3 shows the maximum observable number of sources, $N_{m}$, and the wavelength $\lambda_{m}$ of this maximum, as functions of the telescope diameter $D$. For the range $300 \leq \mathrm{D} \leq 500 \mathrm{ft}$, we find $2.83 \geq \lambda_{\mathrm{m}} \geq 2.45 \mathrm{~cm}$. The demand that $\lambda_{0} \leq 0.75 \lambda_{m}$ from (6) then leads to at least, say

$$
\begin{equation*}
\lambda_{0}<2 \mathrm{~cm} \tag{8}
\end{equation*}
$$

for avoiding severe resolution limitations for future large telescopes.
Table 2 finally summarizes the observational limits of various homologous and other telescopes; $\lambda_{m}$ is given only where it can be observed (if $\lambda_{0} \leq \lambda_{m}$ ) ; $N_{m}$ and $N_{2}$ refer to the actually observable range above $\lambda_{0}$ for resolution-limited telescopes.

In table 2 we see again the importance of short wavelengths. As compared to the NEROC tellescopie, $\mathrm{N}_{2}$ of the homologous $300-\mathrm{ft}$ telescope is larger by a factor of 3.40 , in spite of the smaller telescope diameter; and a homologous telescope of 410 feet diameter would even yield a factor of 7.69 for $\mathrm{N}_{2}$.

Table 2. Observational limits for various telescopes.
D = diameter of telescope;
$\lambda_{0}=$ shortest wavelength of telescope;
$\lambda_{\mathrm{m}}=$ wavelength for maximum number of sources;
$\mathrm{N}_{\mathrm{m}}=$ maximum number of observable sources;
$N_{2}=$ maximum number, where spectrum can be observed through factor 2 in wavelength.
